# Introduction

- Lifetime of a sensor network can be extended by developing query specific plans that limit the data transmitted by the nodes.
  - We consider MAX (or MIN) queries only.  
This query is an example of a more general *exemplary query*:  
where solution consists of one or more representative values as opposed to a summary, where solution is computed over all values.
  - TYPE of query considered:  
Continuous MAX Query
-

---

# Introduction (Contd ...)

- Example Scenarios:
    1. Maintaining maximum temperature in a factory.
    2. Tracking the locations and amounts of highest rainfall across geographic regions.
  
  - Distinction between MAX and Selection Queries is that nodes cannot decide their inclusion in the query result by themselves.
-

---

# Previous Approaches:

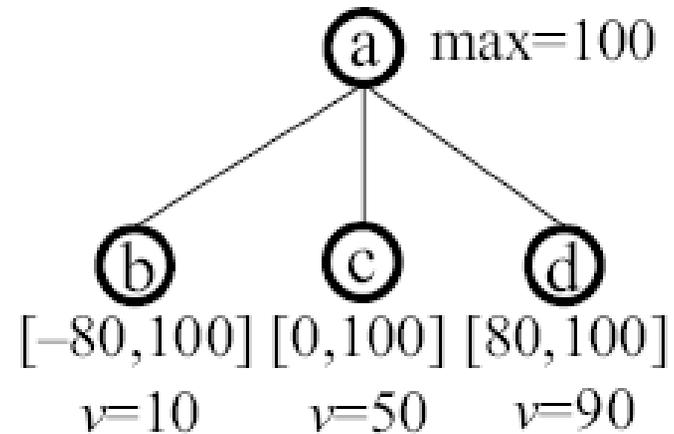

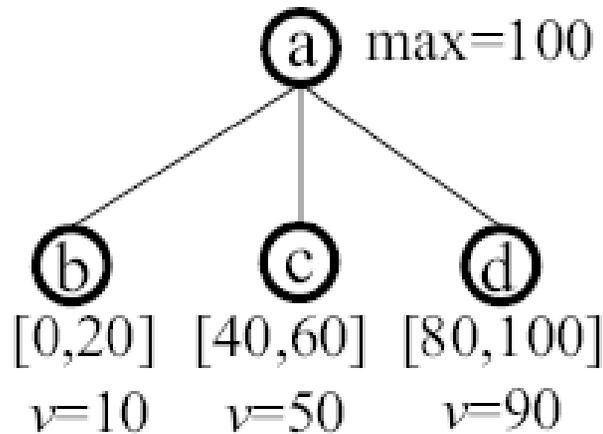

## 1. Temporal Suppression:

A node transmits its value only if it has changed since the last transmission.

## 2. Range Caching:

- The root caches a range for each value at a remote node.
  - The remote node synchronously maintains the same range stored at the root.
  - The node only reports its value if it violates the range.
  - The length of the range controls the trade-off between accuracy and amount of communication between root and the remote node.
-

# Range Caching (Contd ...)

Here max = 100.

Node with v=90 should have smaller range.

---

# Topology-Oblivious Algorithms

- Here we assume all nodes are connected directly to the root in a one-level tree.
  - **Algorithm-1:** Temporal Suppression.
  - **Algorithm-2:** Range Caching
  - **Algorithm-3:** SLAT (Single Layer Adaptive Threshold)
-

# Packet Types used:

Type	Description
<i>Boot</i>	Initial application installation and query
<i>Trigger</i>	Node sending own value
<i>Query</i>	Root initiating fetching of values
<i>Reply</i>	Response to <i>Query</i>
<i>ThresholdUpdate</i>	Update to node constraints
<i>MaxDesignate</i>	Designate node as current max
<i>MaxOff</i>	Notify node that it is no longer max

# Range Caching (Details):

- After receiving Boot packets from root, each node  $u_i$  transmits to the root its value  $v_i$  and a range  $[lb_i, ub_i]$  around  $v_i$ :  
$$v_i = \frac{(lb_i + ub_i)}{2}$$
  - The root maintains the max. value  $v_{\max}$ .
  - In subsequent rounds,  $u_i$  sends a Trigger packet listing  $v_i$  along with a new range if  $v_i$  falls outside  $[lb_i, ub_i]$ .
  - After root gets all the reports, it finds  $v_{\max}$  as follows:
-

# Range Caching (Details):

- Let  $v^*$  = highest reported value.
- Let  $ub^*$  = highest upper-bound of unreported value.
- Let  $lb^*$  = highest lower-bound of unreported value.
  
- If  $v^* > ub^*$ : set  $v_{\max}$  to  $v^*$ .
  
- If  $ub^* > v^*$  or if no nodes reported:  
For each unreported node  $u_i$  with  $ub_i > lb^*$ , root sends query packet requesting  $v_i$ .
  
- The solution is the max. of all reply packets.

# Range Caching (Details):

## Range Adjustment:

- Whenever a node reports its value, it expands the length of its range by a factor  $\alpha > 1$ .
- The new range is then centered at  $v_i$ .
- Whenever a node  $u_i$  is queried by the root:  
It contracts the length of its range by a factor  $\alpha$  with 50% probability.
- In both cases, it transmits  $lb_i$  and  $ub_i$  to synchronize with the root.
- For the node  $u_{\max}$  the range is always set to zero since its value is always required.

---

# Range Adjustment (Contd...)

- Smaller range => Lesser chance of being queried.
  - Larger range => Lesser chance of being required to report.
  - Important nodes contract their range.
  - Unimportant nodes expand their range.
-

# SLAT (Single Layer Adaptive Threshold):

## Initialization:

- Each node  $u_i$  is assigned a threshold  $T_i$  known to both  $u_i$  and root.
- After recv. Boot packet, each  $u_i$  sends  $v_i$  to root and sets  $T_i = v_i$ .
- Root finds the highest reported value =  $v^*$ .
- The one who reported  $v^*$  is  $u_{\max}$ .
- Root sends “MaxDesignate” packet to  $u_{\max}$  and instructs to perform temporal suppression.

# SLAT (Contd ...)

## Invariant-1:

In a particular round, thresholds are set such that for each node  $u_i (\neq u_{\max})$ :  $T_i \leq u_{\max}$ .

## Node-initiated reporting (1<sup>st</sup> stage):

- Max. node does temporal suppression sending Trigger packets when required.
- All other nodes transmit a Trigger packet listing  $v_i$  if  $v_i > T_i$ .

# SLAT (Contd ...)

## Root-initiated querying (2<sup>nd</sup> stage):

- After all nodes have reported, root determines  $v^*$  using all returned values and stored value of  $u_{\max}$  if  $u_{\max}$  did not report.
- Let  $u^*$  be the node with value  $v^*$ .
- If  $v^* \geq$  thresholds of all sensors:  
set  $v_{\max} = v^*$  and  $u_{\max} = u^*$ .
- Or else send Query packet to each  $u_i$  for which  $T_i > v^*$ . The query contains  $v^*$ .

# SLAT (Contd ...)

## Root-initiated querying (2<sup>nd</sup> stage contd ...):

- Each  $u_i$  receiving a Query sends a Reply with its value  $v_i$ , only if  $v_i > v^*$ .
- At root,  $v_{\max}$  is set to max. of all reply packets.
- If no nodes reply,  $v_{\max}$  stays at  $v^*$ .
- If  $u_{\max}$  designation changes, “MaxOff” and “MaxDesignate” packets are sent to old  $u_{\max}$  and new  $u_{\max}$  respectively.

# SLAT (Contd ...)

## Threshold Setting:

- To maintain the invariant, each  $T_i$  must be updated and stored at  $u_i$  and root.
- Whenever  $u_i$  breaks its threshold and sends Trigger to root, it waits for a ThresholdUpdate packet.
- The root transmits  $v_{\max}$  (found in 2<sup>nd</sup> stage) to all  $u_i$  waiting for threshold update.
- $u_i$  updates its  $T_i$  to be halfway between its own value  $v_i$  and  $v_{\max}$ .
- The root does the same thing and updates its own copy of  $T_i$  using  $v_i$  and  $v_{\max}$ . (both are available at the root).

# SLAT (Contd ...)

## Threshold Setting (Contd...):

When a node is queried (in 2<sup>nd</sup> stage), there are 2 cases:

Case 1: If  $v_i > \text{Query Value}$ :  $T_i$  is set to  $v_i$ .

Case 2: If  $v_i < \text{Query Value}$ :

$T_i$  is lowered and set between  $v_i$  and Query Value.

This is also sent to the root in a reply packet.

## Optimization:

If doing so does not lower  $T_i$  much below query value,  $u_i$  has option of setting  $T_i$  to the Query Value and not replying.

---

# SLAT (Contd ...)

## Some Observations:

- Higher Thresholds =>  
Lower reporting + Higher Querying.
  - Lower Thresholds =>  
Higher reporting + Lower Querying.
-

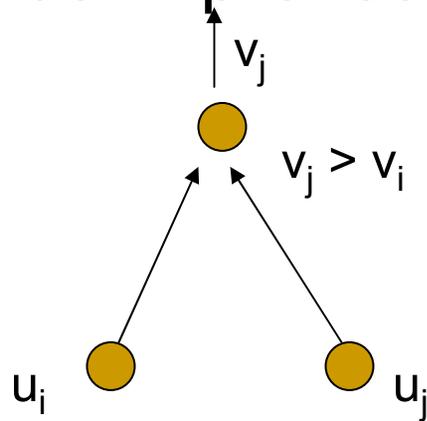

---

# Topology-Aware Algorithms

- These algorithms take into account the routing tree.
  - **Algorithm-1:** SLAT-A (SLAT with Aggregation)
  - **Algorithm-2:** HAT (Hierarchical Adaptive Thresholds)
-

# SLAT-A (Single Layer Adaptive Threshold with Aggregation):

- SLAT transmits all Trigger and Reply packets to the root.
- This can be improved.

- If  $v_j > v_i$  : we drop  $v_i$  and forward only  $v_j$ . (it is impossible for  $v_i$  to be max.)

---

## SLAT-A (Contd ...)

- How to update thresholds in this case?
  - Any node that previously received a Trigger packet from a child must now remember that child.
  - When root sends “ThresholdUpdate” with  $v_{\max}$  to a child, it is sent down the tree recursively to all descendants who had sent a Trigger.
-

---

# SLAT-A (Contd ...)

## **ADVANTAGE:**

**No. of Triggers are reduced.**

## **DISADVANTAGE:**

**Querying by the root is increased.**

(The root does not have information of all thresholds. If the max. value suddenly falls, it has to query many nodes).

This problem is solved by HAT.

---

---

# HAT (Hierarchical Adaptive Threshold):

- Values are only propagated upward until they reach an ancestor with threshold higher than it.
- Queries do not propagate as far downward, and stop at nodes with thresholds below the fallen max. value.

## Invariant-2:

For each node  $u$  having a threshold  $T$  with parent  $u_p$  having threshold  $T_p$ ,  $T \leq T_p$ .

---

# HAT (Contd ...)

## Node-initiated reporting:

- When a node  $u_i$  recv. a trigger from a child node  $u_c$ , it sets a flag indicating  $u_c$  needs threshold update.
- If  $u_i$  either breaks  $T_i$  or recv. from a child a trigger with value  $v_{Tr}$  such that
$$\max\{v_i, \text{all}(v_{Tr})\} > T_i$$
- \* It sends trigger packet to parent  $u_p$ .
- \* Also sends threshold update listing its own value  $v_i$  back to  $u_c$ .
- Here HAT performs additional local filtering compared to SLAT-A based on  $T_i$ .

---

# HAT (Contd ...)

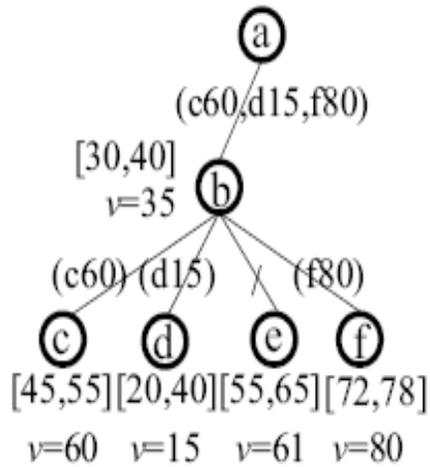

- When node  $u_i$  receives a ThresholdUpdate from its parent listing a value  $v_{TU}$  :  
it modifies its threshold  $T_i$  to within the range  $[\max\{v_i, v_{Tr}\}, v_{TU}]$  i.e. somewhere below the ThresholdUpdate value and above the value that previously caused it to trigger.
  - $u_i$  then sends ThresholdUpdate to all child nodes it has flagged earlier.
-

# HAT (Contd ...)

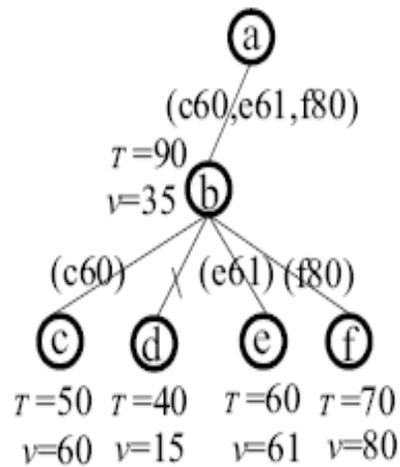

## Root-initiated querying:

- Root first finds  $v^*$ .
- It sends query packets to only those of its child nodes having thresholds  $> v^*$ .
- Each node receiving a query forwards it only to its children having threshold  $> v^*$ .
- Any nodes having value  $> v^*$  sends it in reply packets as before.
- If reply is sent, all nodes from source to the root set their thresholds to the reply value.
- Replies are aggregated just like triggers.

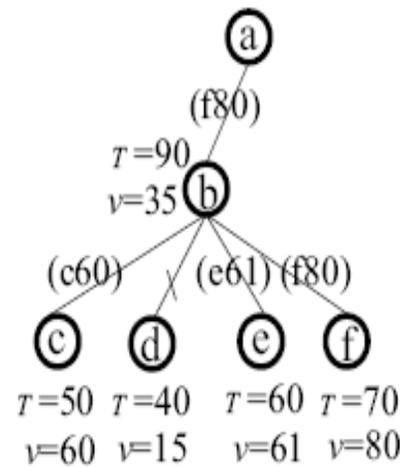

# Comparitive Example:

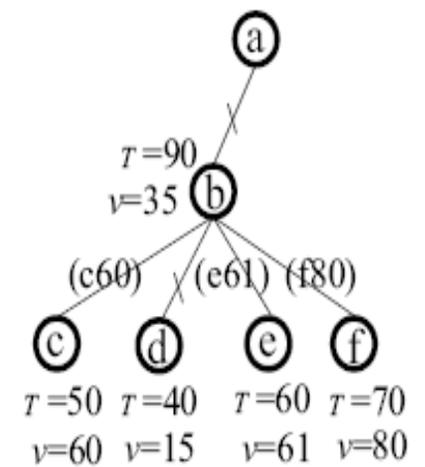

(a) RC

(b) SLAT

(c) SLAT-A

(d) HAT

# Some Results:

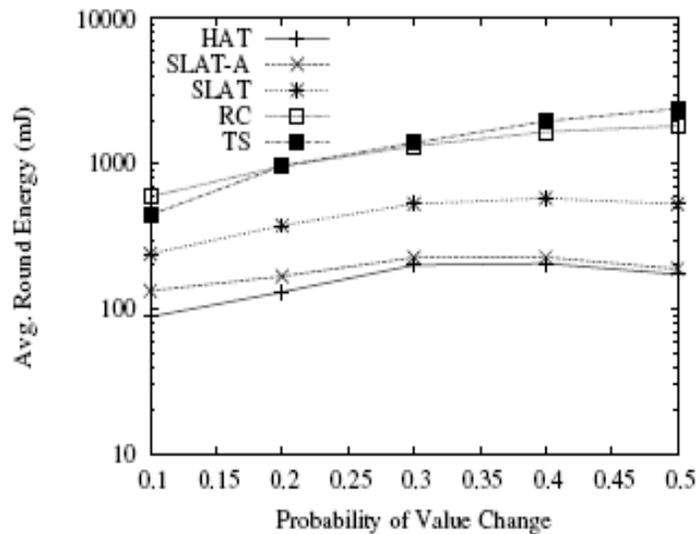

Figure 5: Random behavior.

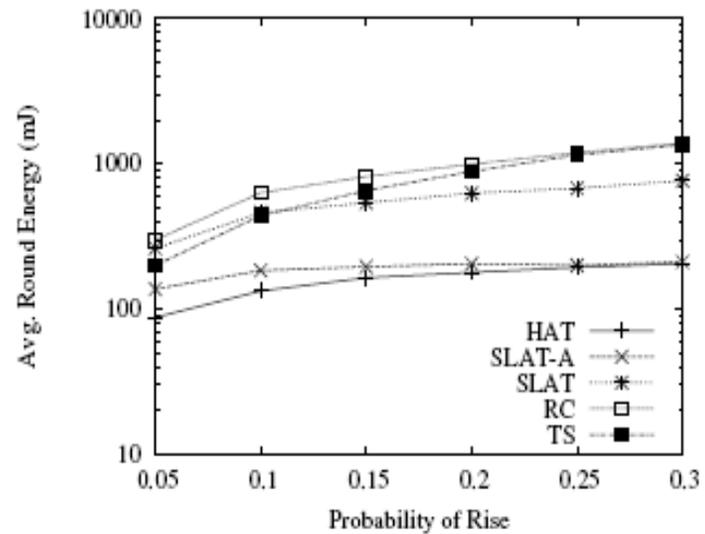

Figure 6: Randomly rising values.
