Abstract

Community detection in networks based on modularity maximization is currently done with hierarchical divisive or agglomerative as well as with partitioning heuristics, hybrids and, in a few papers, exact algorithms. We consider here the case of hierarchical networks in which communities should be detected and propose a divisive heuristic which is locally optimal in the sense that each of the successive bipartitions is done in a provably optimal way. This heuristic is compared with the spectral-based hierarchical divisive heuristic of Newman [Proceedings of the National Academy of Sciences, USA 103, 8577 (2006)] and with the hierarchical agglomerative heuristic of Clauset et al. [Phys. Rev. E 70, 066111 (2004)]. Computational results are given for a series of problems of the literature with up to 4941 vertices and 6594 edges. They show that the proposed divisive heuristic gives better results than the divisive heuristic of Newman and than the agglomerative heuristic of Clauset et al.

I. INTRODUCTION

Networks, or graphs, are a powerful and versatile tool for the study of complex systems, with many applications in computer science, engineering, transportation, sociology, political science, biology, chemistry and other fields. A network consists of a set of vertices (or nodes) and a set of edges (or lines). Vertices are represented by points and associated with entities, such as customers, users of the World Wide Web, employees in an organization, transmitters, road-crossings, railway stations and atoms. Edges are pairs of vertices and represented by a line joining them. The shape of this line is irrelevant; only its presence or absence matters. Edges represent relationships between the entities associated with the vertices: communication, collaboration, existence of a connection such as a road or a railway line and chemical bonds. A detailed introduction to networks has recently been given by Newman [1].

A very important and much studied problem in network science and its applications is the detection of communities (also called modules or clusters). These are sets of entities, or vertices, which are likely to have some common function. Usually, the number of inner edges, i.e., edges joining two vertices of the same community, is larger than the density of outer edges, i.e., edges joining two vertices of different communities. An in-depth survey of the problem of community detection in graphs has recently been given by Fortunato [2]. There are several precise definitions of communities, and corresponding criteria, and many more heuristics as well as a few exact algorithms to find partitions or sets of nested partitions into communities. A heuristic finds a near optimal partition (or sometimes an optimal partition but without proof of its optimality) in moderate time. An exact algorithm finds an optimal partition, with proof of its optimality, hopefully in reasonable time. The most used definition for the quality of a community or of a partition into communities is that of modularity, proposed by Newman and Girvan [3]. Modularity of a community is defined as the difference between the number of edges it contains and the expected number of edges that it would contain if all edges were drawn at random, keeping the same distribution of degrees. The modularity of a partition is the sum of the modularities of its communities. See e.g. [2, 4, 5] for a discussion of the strengths and weaknesses of the modularity function. Given a network and a partition, modularity can be viewed as a measure of the extent to which the classes of the partition can be considered to be communities. Alternatively, given
a network, modularity can be maximized to find an optimal partition, together with its number of clusters and their modularities.

As traditional in Data Analysis, given a set of $n$ entities, clustering heuristics are either hierarchical, i.e., they aim at finding a set of nested partitions, or partitioning schemes, i.e., they aim at finding a single partition (or possibly several partitions into given numbers of clusters). In turn, hierarchical heuristics are divided into agglomerative and divisive ones. Hierarchical agglomerative heuristics [6–10] proceed from an initial partition with $n$ communities each containing a single entity and iteratively merge the pair of entities for which this operation increases most the objective function (e.g., modularity), until all entities belong to the same community. Thus, they find $2n - 1$ communities which are pairwise disjoint or included one into the other. Hierarchical divisive heuristics [11] proceed from an initial partition containing all entities and iteratively divide a community into two in such a way that the increase in the objective function value (e.g., modularity) is the largest possible, or the decrease in the objective value is the smallest possible. Bipartitions are iterated until a partition into $n$ communities having each a single entity is obtained. Thus, once more, $2n - 1$ communities are obtained, which are pairwise disjoint or included one into the other. Note that for some objectives, including modularity, mergings or bipartitions can be ended once they do not improve the objective function value any more.

The partitioning and hybrid heuristics rely upon simulated annealing [12–14], mean field annealing [15], genetic search [16], extremal optimization [17], linear programming followed by randomized rounding [18], dynamical clustering [19], multilevel partitioning [20], contraction-dilation [21], multistep greedy search [22], quantum mechanics [23] and many more [24–28].

Hierarchical heuristics are in principle devised for finding a hierarchy of partitions implicit in the given network when it corresponds to some situation where hierarchy is observed or postulated. Such situations include the description of hierarchies in social organization and networks describing evolutionary processes. Results are presented on a dendrogram which displays visually mergings or divisions of communities together with the values of a characteristic of each community (a variant of the dendrogram, called espalier, allows displaying simultaneously two characteristics of the communities [29]).

The subproblem of choosing at each iteration which pair of communities should be merged is easy. It suffices to consider all $O(n^2)$ merging of pairs of entities and compute each time the
objective function value for the new community. Moreover, a careful use of data structures often reduces complexity. Low order polynomial hierarchical agglomerative heuristics have been obtained in several classical papers. These include \( O(n^2) \) algorithms for single-linkage [30], complete linkage and minimum variance [31] and several others have a complexity of \( O(n^2 \log n) \) [32]. However, in a divisive hierarchical heuristic, the subproblem of finding a bipartition locally optimizing the adopted criterion is more difficult. For some criteria there exists a polynomial algorithm for bipartitioning. For instance, this is the case for the minimum diameter criterion for which there is a \( O(n^2) \) algorithm. With careful use of data structures, this gives a \( O(n^2 \log n) \) locally optimal algorithm for hierarchical divisive clustering with the minimum diameter criterion [33]. The situation is less favorable for the maximum modularity criterion. Indeed, this problem is NP-hard even in the case of two clusters [34]. Nevertheless, as shown below, a non-polynomial algorithm can solve instances with up to 4941 vertices.

We consider only networks with unweighted and undirected edges in the present paper. Its purpose is to propose a locally optimal divisive heuristic for the maximum modularity criterion. To that effect, in the next section the bipartition subproblem is expressed as a quadratic mixed-integer program with a convex relaxation. This problem can then be solved by the \texttt{CPLEX} solver [35]. In Sect. III the full hierarchical divisive algorithm is described as well as the previous spectral hierarchical divisive heuristic of Newman [11] and the fast hierarchical agglomerative heuristic of Clauset, Newman and Moore [7]. A computational comparison of the three heuristics, detailing also the respective contributions of Newman’s spectral results and the Kernighan-Lin heuristic, is given in Sect. IV. Conclusions are drawn in Sect. V.

II. AN EXACT ALGORITHM FOR BIPARTITION

We present in this section an exact algorithm for bipartition with maximization of modularity. We model this bipartitioning problem using binary variables to identify to which community each vertex and each edge belongs. In this respect, our model is similar to that of Xu et al. [36]. These authors proposed in 2007 a modularity maximization model to obtain a partition (generally with more than two communities) of a network. This model is expressed as a mixed integer convex quadratic program. Xu et al. were able to solve exactly
instances with up to 104 vertices.

Let $G = (V, E)$ be a graph, or network, with set of vertices $V$ of order $n = |V|$ and set of edges $E$ of size $m = |E|$. We next recall two equivalent definitions of modularity $Q$. In the first one, it is expressed as a sum over communities of their modularities [3]:

$$Q = \sum_s [a_s - e_s],$$

where $a_s$ is the fraction of all edges that lie within community $s$ and $e_s$ is the expected value of the same quantity in a graph in which the vertices have the same degrees but edges are placed at random. In the second one, modularity $Q$ is expressed as a function, for each community, of its number of inner edges and of the sum of degrees of its vertices:

$$Q = \sum_s \left[ \frac{m_s}{m} - \left( \frac{d_s}{2m} \right)^2 \right],$$

where $m_s$ denotes the number of edges in community $s$, i.e., the subgraph $G_s = (V_s, E_s)$ with set of vertices $V_s \subset V$ and set of edges $E_s$ having both vertices in $V_s$, and $d_s$ denotes the sum of degrees $k_i$ of the vertices of community $s$. Since we aim to find a bipartition, only two sub-modules of the original community have to be considered, i.e., $s \in \{1, 2\}$. We can express the sum of degrees $d_2$ of vertices belonging to the second community as a function of the sum of degrees $d_1$ of vertices belonging to the first one:

$$d_2 = d_t - d_1,$$

where $d_t$ is the sum of degrees in the community to be bipartitioned and it is equal to $2m$ at the outset. We rewrite (1) for $s \in \{1, 2\}$, using (2):

$$Q = \frac{m_1 + m_2}{m} - \frac{d_1^2}{4m^2} - \frac{d_2^2}{4m^2} = \frac{m_1 + m_2}{m} - \frac{d_1^2}{4m^2} - \frac{d_2^2}{4m^2} + \frac{d_1^2 - 2d_t d_1}{4m^2} = \frac{m_1 + m_2}{m} - \frac{d_1^2}{2m^2} - \frac{d_2^2}{4m^2} + \frac{d_t d_1}{2m^2}. $$

We then introduce binary variables $X_{r1}, X_{r2}$ and $Y_{it}$ to model the assignment of vertices and edges to the two communities of the bipartition. These variables are defined as follows:

$$X_{rs} = \begin{cases} 1 & \text{if edge } r \text{ belongs to community } s \\ 0 & \text{otherwise} \end{cases}$$
for \( r = 1, 2, \ldots, m \) and \( s = 1, 2 \) and

\[
Y_{i1} = \begin{cases} 
1 & \text{if vertex } i \text{ belongs to community 1} \\
0 & \text{otherwise, i.e. if vertex } i \text{ belongs to community 2} 
\end{cases}
\] (5)

for \( i = 1, 2, \ldots, n \). Two sets of variables \( X_{r1} \) and \( X_{r2} \) are needed as an edge may belong to the first community, or to the second one, or be a bridge between both of them. One set of variables \( Y_{i1} \) suffices as any vertex which does not belong to the first community must belong to the second.

Moreover, we impose for consistency that any edge \( r = \{v_i, v_j\} \) with end vertices indexed by \( i \) and \( j \) can only belong to community \( s \) if both of its end vertices belong also to that community:

\[
X_{r1} \leq Y_{i1} \quad \forall r = \{v_i, v_j\} \in E
\] (6)

and

\[
X_{r1} \leq Y_{j1} \quad \forall r = \{v_i, v_j\} \in E
\]

\[
X_{r2} \leq 1 - Y_{i1} \quad \forall r = \{v_i, v_j\} \in E
\]

\[
X_{r2} \leq 1 - Y_{j1} \quad \forall r = \{v_i, v_j\} \in E.
\] (7)

Furthermore, we exploit the following expressions in terms of variables \( X \) and \( Y \) for the number of edges of each of the two communities and the sum of vertex degrees of the first one:

\[
m_s = \sum_r X_{rs} \quad \forall s \in \{1, 2\},
\] (8)

\[
d_1 = \sum_{i \in V_1} k_i Y_{i1}.
\] (9)

The sum of vertex degrees of the first community only is needed, because of expression (2).

Maximizing modularity (3) subject to constraints (6)-(7) and (8)-(9) gives a quadratic convex mixed-integer program that can be solved by CPLEX [35]. Indeed, this model contains a single nonlinear but concave term, i.e., \(-d_1^2/2m^2\), in the objective function, which is to be maximized. Hence, its continuous relaxation, obtained by removing the integrality constraints on the variables, is a convex quadratic program and easy to solve.

Note that in Xu et al.’s [36] model a number of other constraints are imposed. For instance, constraints are used to express that community \( s \) can be nonempty only if community \( s - 1 \) is so, and lower and upper bounds on the cardinality of the modules are added as an option. Furthermore, symmetry-breaking constraints avoid the computation of equivalent alternative optimal solutions.
III. HEURISTICS

In this section, we first recall the hierarchical agglomerative heuristic of Clauset, Newman and Moore [7] (CNM), and the hierarchical divisive spectral heuristic of Newman [11] (divisive spectral), to which we compare the heuristic of the present paper. We then describe the new heuristic itself.

The CNM heuristic fits into the general scheme for hierarchical agglomerative heuristics of cluster analysis [32]. It can therefore be implemented with a complexity of $O(n^2 \log n)$ in worst case. However, a careful exploitation of sparsity of the graph under study reduces its worst-case complexity to $O(m \log n)$ and its complexity in practice to $O(n \log^2 n)$, which is close to linear time. Results in terms of partitions and the dendrograms obtained are the same for both implementations. The CNM heuristic proceeds from an initial partition with $n$ clusters each containing a single entity. Then, it merges iteratively the two clusters in the current partition for which the modularity increases the most. The formula

\[
\Delta Q_{ij} = \begin{cases} 
1/2m - k_i k_j / (2m) & \text{if } v_i, v_j \text{ are connected} \\
0 & \text{otherwise}
\end{cases}
\]

is used initially, then the $\Delta Q_{ij}$ for all edges are updated each in constant time. Mergings take place as long as the best of them increases modularity (or, in other words, there is a positive $\Delta Q_{ij}$).

Two remarks are in order. First, in hierarchical agglomerative heuristics, errors, i.e., assignment of two entities to the same cluster while they should be in different clusters in the (or all) optimal partition(s), are never corrected. Second, as $n$ is usually much larger than the number of clusters in the optimal partition, there are close to $n$ mergings before reaching the best partition obtained by the heuristic and hence many occasions of error.

The hierarchical divisive heuristic of Newman proceeds from an initial partition containing all entities by iteratively splitting one of its clusters, as long as this operation increments modularity. Two questions have to be answered to specify this heuristic: which cluster should be selected for splitting at each iteration and how should the splitting be made. The answer to the former question is unimportant as the best partition obtained does not depend on the order of the splittings but only on the way they are performed. The second question is difficult: indeed, finding the optimal, i.e., modularity maximizing, splitting of a cluster contains the problem of maximum modularity bipartition, which, as shown by Brandes et
al. [34], is NP-hard.

For large instances, splitting will have to be done in a heuristic way. Newman [11] proposes two ways to do so. The first is based on spectral graph theory. The first eigenvector of the modularity matrix \( B = (b_{ij}) \) with

\[
b_{ij} = a_{ij} - k_i k_j / 2m
\]

is computed. The entities corresponding to positive components of this eigenvector form one community and the remaining ones the other.

Results of splitting according to the first eigenvector can be improved by a variety of heuristics. Newman suggests the use of the Kernighan-Lin heuristic [37]. This heuristic proceeds from an initial bipartition to a sequence of re-assignments of one entity from a community to the other. At each step the re-assignment which improves most, or deteriorates least, the objective function value, is selected, performed and further re-assignments of the moved entity forbidden. Once no more re-assignments are allowed, the best partition found among the \( n \) partitions considered in the sequence is selected as new initial partition. The whole procedure stops when a full sequence of \( n \) re-assignments does not lead to any improvement.

Again two remarks are in order. First, errors, i.e., assigning two entities to different communities when both belong to the same community in the optimal partition are never corrected. Second, as the number of communities in the optimal partition tends to be small, few splittings will take place and thus there are few occasions for errors to be made.

The heuristic of the present paper proceeds along the same lines as the hierarchical divisive heuristic of Newman. The difference is that the exact bipartitioning method of Sect. II is used for the splitting step. Due to the difficulty of this subproblem and present limitations of nonlinear integer programming, the exact bipartitioning could be applied only to small or medium-size networks with up to 4941 vertices. The proposed heuristic is locally optimal in that the splitting step is done optimally, but not globally optimal in that the new heuristic is a greedy one, i.e., each splitting step is done without considering the consequences on further steps, but better results might be obtained if this was done. Note that there are some cases where a greedy heuristic is optimal, the best known one in the field of cluster analysis being the single-linkage heuristic which maximizes the split (or minimum dissimilarity between pairs of entities in different communities) of the partitions obtained at all levels [30, 38].
This is not the case for the proposed hierarchical divisive heuristic, as shown by an example in Sect. IV.

IV. COMPUTATIONAL RESULTS

In all experiments, we considered a set of 12 well known problems from the literature. They are listed together with their order $n$ and size $m$ in the first three columns of Table I. They are all undirected and unweighted networks without loops. All data are available on sites listed in [39]. Optimal solutions of these test problems are given in [40]. The bipartition subproblem is solved using CPLEX [35]. Other solvers for convex mixed-integer quadratic programs did not perform as well in preliminary tests.

In a first series of experiments, we compared the maximum modularity values and the corresponding number of clusters for the hierarchical agglomerative heuristic of Clauset et al. [7], and for the locally optimal divisive heuristic of the present paper. We also list maximum modularity and number of clusters obtained by an exact algorithm of [40], when possible, i.e., for datasets from 1 to 11. The modularity obtained by the proposed divisive heuristic $CHL$ for the 12th dataset is 0.9394. This appears to be the best value currently known for this dataset. Indeed, using the best heuristic from the extensive comparison by Noack and Rotta [39], gives a value of 0.93854.

It appears that:

- The locally optimal hierarchical divisive heuristic always gives partitions with smaller modularity than the exact algorithm. The difference, however, is moderate and goes from 0.18018% to 2.36603% of the optimal value. The average error is 0.82540%.

- The agglomerative heuristic always gives partitions with smaller modularity than the divisive one and, by transitivity, than the exact one. The difference this time is much more substantial and goes from 1.21494% to 12.9848%, relative to the exact solution. The average error is 5.52342%. The error between the divisive and the agglomerative heuristics goes from 0.780214% to 10.9013% of the value obtained by the divisive heuristic. The average error is 4.75179%, which is again substantial.

- The divisive heuristic gives a partition with fewer communities than the exact one in 3 cases out of 11, the same number in 3 cases and a larger number in the remaining
5 cases. The average number of communities obtained with the divisive heuristic is 9.27273 vs. 8.81818 for the exact method, so it is slightly in excess.

- The agglomerative heuristic gives a partition with fewer communities than the exact one in 7 cases out of 11, a partition with the same number of communities than the exact one in 2 cases out of 11, and a partition with more communities in the remaining 2 cases. The average number of communities obtained with the agglomerative heuristic is 8 vs. 8.81818 for the exact method, so somewhat smaller.

In a second series of experiments we compared the divisive heuristic of the present paper with the previous divisive heuristic of Newman [11]. To better understand the performance of Newman’s heuristic, we consider three versions of it. In the first one, the bipartition at each iteration is done solely on the basis of the leading eigenvector of the modularity matrix. In the second one, the Kernighan-Lin heuristic is applied at each iteration to a randomly generated solution. In the third one, the Kernighan-Lin heuristic is applied at each iteration to the solution given by the leading eigenvector. Results are presented in Tables II,III,IV. It appears that

- the first version always gives partitions with substantially smaller modularities than the divisive heuristic of the present paper or the exact algorithm. The error relative to the partition given by the exact algorithm goes from 5.81428% to 18.5189%. The average error is 10.7419%. The error relative to the partition given by the divisive heuristic of the present paper goes from 5.63859% to 18.0227%. The average error is 9.99712%.

- The second version gives results even worse than those of the first version. The error relative to the partition given by the exact algorithm goes from 5.95934% to 28.6442%. The average error is 14.5856%.

- The third version gives better results The error relative to the partition given by the exact algorithm goes from 0.09863% to 6.07995%. The average error is 3.02627%. The error relative to the partition given by the divisive heuristic of the present paper goes from −0.081704% to 5.46305%. The average error is 2.21592%. Observe that in the case of the political books instance, the modularity obtained with the divisive spectral + KL heuristic, i.e., 0.52672, is slightly better than that one obtained with
the heuristic of the present paper, i.e., 0.52629. This is not a numerical error but illustrates, as mentioned above, that the proposed heuristic is locally but not globally optimal. The observation that version 3 is better than version 1 and that version 1 is better than version 2 was already made by Newman [11].

- Computing times of the heuristic proposed in this paper and an exact column generation algorithm for modularity maximization of [40] are given in Table V. As the computers used are not the same for the two cases, these results should only be considered as indicative. Ratios between these computing times are given in the last column. The time of the heuristic CHL is less than the time of the exact algorithm in 9 cases over 12 and in several cases very substantially so. Moreover, the heuristic could solve the last problem, which is about 10 times larger than the penultimate, in reasonable time, while the exact algorithm could not.

- Currently, it is not possible to solve very large instances with the heuristic of the present paper or large ones with the exact column generation algorithm for modularity maximization of [40]. One cannot therefore be sure that the differences in performances between the heuristics described above and/or the exact algorithm extend to the resolution of large instances, except in a few cases. A comparison between the agglomerative heuristic CNM and the complete version of the divisive heuristic of Newman is part of Table 1 of [11]. The corresponding columns are reproduced in Table VI, together with the percentage errors in the modularities obtained. This confirms that the agglomerative heuristic of Clauset et al. gives poor results for small as well as for large instances.

V. CONCLUSIONS

In this paper we presented a hierarchical divisive heuristic for modularity maximization which is locally optimal, i.e., such that the bipartition obtained at each iteration is guaranteed to be optimal. This heuristic can be used for two purposes: approximate modularity maximization of general networks or modularity maximization of networks which are known to correspond to some hierarchy either natural or man made. In the former case, experimental results show that the partitions obtained with the proposed divisive heuristic tend
to have a modularity value close to that of optimal partitions (recall that the average error observed in our experiments is 0.82540%). So, the partition found can be considered as a fairly good approximation of the optimal one, or at least as a tentative solution to be improved upon by various local improvement heuristics.

Our experiments also show that modularity maximization with the hierarchical agglomerative heuristic of Clauset, Newman and Moore tends to have a much larger error (with an average error of 5.52342% for our experiments).

Our heuristic is tailored for the latter case. We therefore compared it with three versions of the divisive heuristic of Newman. As observed by that author, a two-phase method in which a first bipartition is made in a splitting step on the basis of the first eigenvector of the modularity matrix followed by application of the Kernighan-Lin heuristic gives the best results. Still, the proposed heuristic appears to be even better, indeed the average error relative to the exact solution is reduced more than threefold, i.e., from 3.02627% to 0.82540%.

TABLE I: Comparison of results of Clauset et al.’s heuristic (CNM), the proposed locally optimal divisive heuristic (divisive CHL), and an exact algorithm for modularity maximization [40] (exact) on real world datasets. $M$ denotes the number of communities and $Q$ the modularity value of the best solution found. $error(\%)$ denotes the percentage error for the two heuristics with respect to the exact algorithm. Average values are given for the first 11 datasets as the 12-th one cannot be solved exactly in reasonable time. $n$ and $m$ are the number of vertices and the number of edges of the networks. We consider Zachary’s karate club dataset [41] describing friendship relationships between members of a club, Lusseau’s dolphins dataset [42] describing communications between dolphins in Doubtful Sound New Zealand, Hugo’s Les Misérables dataset describing characters in Victor Hugo’s masterpiece and their interactions, compiled by Knuth [43], a dataset (A00_main) on classes and relationships from a software project related to Graph Drawing [44], a network dealing with protein interactions [45], Krebs’ political books dataset [46], a dataset representing the schedule of football games between American college teams [47], another dataset on classes and relationships from a software project [44], a network dealing with connections between US airports [48], a dataset on a coauthorship network of scientists working on network theory and experiment, compiled by M. Newman [49], a network describing electronic circuits [50] and a network representing the topology of the Western States Power Grid of the United States [51].

TABLE II: Comparison of results of Newman’s spectral divisive heuristic (divisive spectral), the proposed locally optimal divisive heuristic (divisive CHL), and an exact algorithm for modularity maximization [40] (exact) on real world datasets. M denotes the number of communities and Q the modularity value of the best found solution. error(%) denotes the percentage error for the two heuristic with respect to the exact algorithm. Average values are given for the first 11 datasets as the 12-th one cannot be solved exactly in reasonable time. n and m are the number of vertices and the number of edges of the networks.

**TABLE III:** Comparison of results of the divisive Kernighan-Lin based heuristic (KL), the proposed locally optimal divisive heuristic (divisive CHL), and an exact algorithm for modularity maximization [40] (exact) on real world datasets. M denotes the number of communities and Q the modularity value of the best found solution. error(%) denotes the percentage error for the two heuristics with respect to the exact algorithm. Average values are given for the first 11 datasets as the 12-th one cannot be solved exactly in reasonable time. n and m are the number of vertices and the number of edges of the networks. Note that values of Q and error percentage are given with less digits that elsewhere in this paper due to the fact that the Kernighan-Lin heuristic depends upon the random partition to which it is applied.
TABLE IV: Comparison of results of Newman’s spectral divisive heuristic with the Kernighan-Lin refinement (divisive spectral + KL), the proposed locally optimal divisive heuristic (divisive CHL), and an exact algorithm for modularity maximization [40] (exact) on real world datasets. \( M \) denotes the number of communities and \( Q \) the modularity value of the best found solution. \( \text{error}(\%) \) denotes the percentage error for the two heuristics divisive spectral + KL and divisive with respect to the exact algorithm. \( \text{error}_{\text{div}}(\%) \) denotes the percentage error for the divisive spectral + KL with respect to the proposed locally optimal heuristic. Average values are given for the first 11 datasets as the 12-th one cannot be solved exactly in reasonable time. \( n \) and \( m \) are the number of vertices and the number of edges of the networks. Note that values of \( Q \) and error percentage are given with less digits that elsewhere in this paper due to the fact that the Kernighan-Lin heuristic depends upon the random partition to which it is applied.

TABLE V: Comparison of times for the proposed locally optimal heuristic and an exact algorithm for modularity maximization. All results are in seconds of CPU. Solutions obtained with the proposed heuristic were obtained on a 2.4 GHz Intel Xeon CPU of a computer with 8GB RAM shared by three other similar CPU running Linux. Solutions obtained with the exact algorithm were obtained on a dual processor computer Intel Pentium with 3.20 GHz, 3GB RAM running Linux.

TABLE VI: Comparison of results [11] of the Clauset et al.’s agglomerative heuristic (agglomerative CNM) and Newman’s spectral divisive heuristic with the Kernighan-Lin refinement (divisive spectral + KL). $Q$ denotes the modularity value of the best found solution. error(%) denotes the percentage error for the first heuristic with respect to the second one. $n$ is the number of vertices. Jazz dataset describes musicians which worked together [52], metabolic dataset describes chemical reactions as well as the regulatory interactions that guide these reactions in C. elegans [53], e-mail dataset describes e-mail interchanges between members of a university [54], key signing (PGP) dataset describes the giant component of the network of users of the Pretty-Good-Privacy algorithm for secure information interchange [55], physicists (cond-mat) dataset describes a collaboration network of scientists posting preprints on the condensed matter archive [56].
