Abstract: Component substitution (CS) and multi-resolution analysis (MRA) are the two basic categories in the extended general image fusion (EGIF) framework for fusing panchromatic (Pan) and multispectral (MS) images. Despite of the method diversity, there are some unaddressed questions and contradictory conclusions about fusion. For example, is the spatial enhancement of CS methods better than MRA methods? Is spatial enhancement and spectral preservation competitive? How to achieve spectral consistency defined by Wald et al. in 1997? In their definition any synthetic image should be as identical as possible to the original image once degraded to its original resolution. To answer these questions, this research first finds out that all the CS and MRA methods can be derived from the Bayesian fusion method by adjusting a weight parameter to balance contributions from the spatial injection and spectral preservation models. The spectral preservation model assumes a Gaussian distribution of the desired high-resolution MS images, with the up-sampled low-resolution MS images comprising the mean value. The spatial injection model assumes a linear correlation between Pan and MS images. Thus the spatial enhancement depends on the weight parameter but is irrelevant of which category (i.e., MRA or CS) the method belongs to. This paper then adds a spectral consistency model in the Bayesian fusion framework to guarantee Wald’s spectral consistency with
regard to arbitrary sensor point spread function. Although the spectral preservation in the EGIF methods is competitive to spatial enhancement, the Wald’s spectral consistency property is complementary with spatial enhancement. We conducted experiments on satellite images acquired by the QuickBird and WorldView-2 satellites to confirm our analysis, and found that the performance of the traditional EGIF methods improved significantly after adding the spectral consistency model.

---

1. Introduction

With the development of science and technology, remote sensing data have exhibited explosive growth trends for multi-sensor, multi-temporal and multi-resolution characteristics. However, there are contradictions between the resolution limitations of current remote sensing systems and the increasing need for high-spatial, high-temporal and high-spectrum resolutions of satellite images [1]. One limitation is the spectral and spatial resolution tradeoff, as more than 70% of current optical earth observation satellites simultaneously collect low-spatial resolution (LR) multispectral (MS) and high-spatial resolution (HR) panchromatic (Pan) images [2]. This tradeoff will survive in forthcoming hyperspectral and MS sensors such as WorldView-3, EnMAP, PRISMA and HypIIRI [3]. Based on information fusion theory, satellite image fusion has been proposed to handle these limitations [4,5]. Pansharpening, which is a spatial and spectral fusion method, focuses on enhancing LR MS images using the Pan image to obtain both high-spatial and high-spectral resolution images [6]. Despite the variety of current pansharpening methods, they can generally be classified into component substitution (CS) and multi-resolution analysis (MRA) methods. Both the CS and MRA methods have been generalized into the extended general fusion framework (EGIF) [7,8].

Many studies have focused on comparing and reviewing these methods [4,5,8–23] and had several common findings. First, among the CS methods, the Gram-Schmidt (GS) algorithm [24] was found to be the best in terms of spectral preservation and spatial injection [2,7,25]. Second, among the MRA methods, the generalized Laplacian pyramid (GLP) has been shown to present advantages, as it can adapt to the sensor point spread function (PSF) [15,26–28]. Finally, a current trend of pansharpening methods is to preserve the spectral information of the original MS images. This preservation is accomplished in two ways. First, CS methods are either adopted on their own to create an ideal intensity by accounting for the spectral response functions or using linear regression technology [25,29–31], or combined with MRA methods [32–34]. Second, MRA methods are adopted to modulate high frequencies using global or local injection models [23,35] such as AABP (an acronym formed from its authors’ initials, i.e., Alazii, Alparone, Baronti and Pippi [36]), high-pass modulation (HPM) [37], context-based decision (CBD) [15,28], enhanced CBD [27], proportional additive wavelet LHS (intensity-hue-saturation) [38] and Model 3 (M3) [39]. Despite these findings, pansharpening remains a source of confusion and unaddressed questions, which are listed as follows.
Question 1: The relationship between the CS and MRA methods is not well understood. According to the EGIF, the only difference between CS and MRA methods is how to extract the spatial details. And the injection models to control the spatial detail injection amount utilized by the CS and MRA methods are similar [7]. Thus the enhancement of CS methods should be comparable to that of MRA methods. However, there are some studies which observed that the spatial enhancement of CS methods is larger than that of MRA methods [27,40–42].

Question 2: There is a contradicting conclusion on the existence of the spatial enhancement and spectral preservation tradeoff in the fused images. Many CS method developers believed this tradeoff and tried to balance this tradeoff by introducing weight parameters to control the spatial injection [41,43,44]. Some MRA method developers implicitly assumed this tradeoff as they used optimization technologies with competitive objectives, i.e., to maximize the spatial similarity to the Pan image and the spectral similarity to the up-sampled MS images [45] to determine the best injection model [45–47]. Furthermore, in the MRA and CS comparison studies, researchers have found that although the spatial enhancement of CS methods is better than that of MRA methods [40–42], the spectral preservation of the former is worse. This indeed enhances the fidelity of the tradeoff quality in fused images [17,48,49]. However, Thomas et al. [10] challenged the existence of the tradeoff by stating that “this tradeoff is a consequence of the use of certain tools and not an a priori compulsory”. They claimed that it cannot be reduced to the spatial information of its associated spectral information in an image. As such, the question remains: does the tradeoff really exist?

In fact, the question 2 originates from that the implicit spectral preservation definition in current pansharpening algorithms is improper. In pansharpening algorithms, the spectral preservation is defined to be as identical as possible to the up-sampled MS images. We will prove that from a Baysian perspective that all the EGIF methods have used the MS image as prior knowledge to preserve spectral information although only a few have explicitly stated that. For example, some intensity-hue-saturation-based (IHS-based) methods for spectral preservation have been developed by maintaining the saturation of the up-sampled MS images [29,41,50]. Some MRA methods indicate that if the Pan and MS images exhibit a low correlation, the up-sampled images can be used as a fused product for preserving spectral information [10,28,47]. In contrast, as observed by Wald et al. [51], spectral consistency infers that any synthetic image degraded to its original resolution with respect to the sensor PSF should be as identical as possible to the original image [51,52]. Recently, Chen et al. [53] have noticed the upsampled MS image (used in EGIF) is not as accurate as the original MS image (defined by Wald) for preserving the spectral information. The questions are how to guarantee spectral consistency with Wald’s definition with arbitrary sensor PSF and how much the methods can be improved if spectral consistency is achieved.

In this paper, we find that the CS and MRA methods are special cases of the Bayesian data fusion method. And all of the preceding questions can be answered by interpreting fusion from a Bayesian perspective. Bayesian data fusion methods are rooted in image formulation models and consider the fusion process as an inverse problem [54–57]. It includes two steps, the modeling step to build the equations and the inversion step to find the solution. Interpreting fusion from a Bayesian data fusion framework can answer these questions due to its explicit assumptions in modeling process and its flexibility in inverse process. The modeling step is easy to interpret with explicit assumptions and thus we can find out what are the assumptions used in EGIF. And the diversity of the optimization technology provides more flexibility to solve the complicated models which cannot be solved in EGIF, i.e., to guarantee spectral consistency with regard to arbitrary sensor PSF.
1.1. Image Fusion from a Bayesian Perspective

We interpret the fusion from a Bayesian perspective with images in vector form and operations on images in matrix form. Although the deduction process may not be straightforward by the vector and matrix forms, the benefits lie in interpreting the fusion more easily. We assume that each LR image has \( M \) pixels and that each HR image has \( N \) pixels. As such, \( N = r^2M \), where \( r \) is the spatial resolution ratio. The desired HR MS images with \( Q \) spectral bands in band-interleaved-by-pixel lexicographical notation is denoted as a vector with \( NQ \) elements, \( \mathbf{Z} = [\mathbf{Z}_1, \mathbf{Z}_2, \ldots, \mathbf{Z}_n]^\top \). The observed HR Pan image is denoted as a vector with \( N \) elements, \( \mathbf{X} = [X_1, X_2, \ldots, X_N]^\top \). \( \mathbf{Z}_n = [\mathbf{Z}_n^1, \mathbf{Z}_n^2, \ldots, \mathbf{Z}_n^Q]^\top \) is the spectra at the spatial location \( n \) \((n = 1, 2, \ldots, N)\). The corresponding LR versions of \( \mathbf{Z} \) and \( \mathbf{X} \) in lexicographical form are denoted as \( \mathbf{z} \) and \( \mathbf{x} \) respectively, and comprise only \( M \) pixels.

In terms of notations of this paper we use boldface upper- and lowercase letters to differentiate matrices and vectors. However, in one exception, the HR MS and Pan image vectors are denoted as \( \mathbf{Z} \) and \( \mathbf{X} \) (in both italics and bold) to correspond with LR vectors \( \mathbf{z} \) and \( \mathbf{x} \). \( \hat{\mathbf{z}} \) and \( \hat{\mathbf{x}} \) represent the up-sampled MS and Pan images, respectively, and have the same dimensions as the HR images. Denote \( \mathbf{Z}^i = [\mathbf{Z}_1^i, \mathbf{Z}_2^i, \ldots, \mathbf{Z}_n^i]^\top \) as the spectra vector of the band \( q \), for \( q = 1, 2, \ldots, Q \). \( \hat{\mathbf{z}}^i \) and \( \hat{\mathbf{z}}^i \) can be similarly defined. The superscript \( q \) indicates the \( q \)th band and the subscript \( n \) indicates the \( n \)th pixel in the following analysis.

Treating the observed vectors, \( i.e., \mathbf{z} \) and \( \mathbf{X} \), and the vector to be estimated, \( i.e., \mathbf{Z} \), as random vectors, the maximum \( a \) \( \text{posteriori} \) (MAP) estimate is given by a vector \( \hat{\mathbf{Z}} \), which maximizes the conditional probability density function of \( \mathbf{Z} \) given \( \mathbf{X} \) and \( \mathbf{z} \), \( p(\mathbf{Z}|\mathbf{X}, \mathbf{z}) \). Applying the Bayes rule, we obtain.

\[
p(\mathbf{Z} \mid \mathbf{X}, \mathbf{z}) = \frac{p(\mathbf{X}, \mathbf{z} \mid \mathbf{Z})p(\mathbf{Z})}{p(\mathbf{X}, \mathbf{z})}
\]

(1)

1.2. Spectral Consistency, Spectral Preservation and Spatial Injection Models: Modeling Step

(1) Firstly, the observation model \( h \) correlates the LR and HR MS images, \( \mathbf{z} \) and \( \mathbf{Z} \), which mathematically describes the spectral consistency defined by Wald \( et \) \( al. \) [51]:

\[
\mathbf{z} = h(\mathbf{Z}) + \mathbf{n} = \mathbf{HZ} + \mathbf{n}
\]

(2)

where \( \mathbf{H} \) is a matrix with \((QM) \times (QN)\) elements representing the low-pass filtering and down-sampling process, and \( \mathbf{n} \) is the random noise vector with \(QM\) elements. \( \mathbf{Z} \) denotes the desirable HR MS images that are assumed to be the real scene without any blur. Thus, the specific sensor PSF, \( i.e., \) the blur effect, should be modeled in the \( \mathbf{H} \) matrix. \( \mathbf{H} \) usually comprises at least two parts: at least one image filtering matrix representing the blur PSF and at least one image down-sampling matrix to change the dimension of \( \mathbf{Z} \) to that of \( \mathbf{z} \). For example, in a PSF case simulated by a two-level “à trous” wavelet (ATW) transformation filter [28] with a scale ratio of \( r = 4 \), there are two filtering matrices and two down-sampling matrices, respectively:

\[
\mathbf{H} = \mathbf{D}_2 \mathbf{F}_2 \mathbf{D}_1 \mathbf{F}_1
\]

(3)

where \( \mathbf{F} \) is the ATW filter \( (\mathbf{F}_1 \text{ with } (QN) \times (QN) \text{ elements and } \mathbf{F}_2 \text{ with } (QN/2) \times (QN/2) \text{ elements}) \) and \( \mathbf{D} \) is the down-sampling process by two \( (\mathbf{D}_1 \text{ with } (QN/2) \times QN \text{ elements and } \mathbf{D}_2 \text{ with } QM \times (QN/2) \text{ elements}) \). \( \mathbf{D} \) and \( \mathbf{F} \) require a huge storage space, \( i.e., \) more than \( M \) times that required for storing the MS images \( \mathbf{Z} \). In our final solution, we find that the \( \mathbf{H} \) matrix and \( \mathbf{Z} \) vectors do not have to be formed, and that the solution can be expressed in image form (see the discussion in Sections 1.5, 1.6 and 2.6).
Secondly, the relationship between the observed Pan image $X$ and the MS images $Z$ is represented by $g(Z)$:

$$X = g(Z) + e$$

(4)

where $e$ is a vector of random errors with $N$ elements. We usually assume that they are linearly correlated:

$$g = a + eXZ$$

(5)

where $B$ is a coefficient matrix with $N \times (QN)$ elements and $a$ is a coefficient vector with $N$ elements. We will prove later that this model mainly related to the spatial detail injection in EGIF.

Finally, we assume that $Z$ is a Gaussian vector with a mean vector $\bar{z}$ and covariance matrix $C_{Z}$, with $QN \times QN$ elements. This is a very important assumption as it can roughly satisfy the spectral preservation requirement using the up-sampled MS images as the mean value. It is simply referred to as the Gaussian assumption of the MS images.

Denoting the covariance matrices of $e$ and $n$ as $C_{e}$ with $N \times N$ elements and $C_{n}$ with $QM \times QM$ elements, respectively, we have:

$$p(z|Z) = (2\pi)^{-\frac{MQ}{2}}(C_{n})^{-\frac{1}{2}}\exp\left\{-\frac{1}{2}(z - HZ)^{T}C_{n}^{-1}(z - HZ)\right\}$$

(6)

$$p(X|Z) = (2\pi)^{-\frac{N}{2}}(C_{e})^{-\frac{1}{2}}\exp\left\{-\frac{1}{2}(X - g(Z))^{T}C_{e}^{-1}(X - g(Z))\right\}$$

(7)

$$p(Z) = (2\pi)^{-\frac{NQ}{2}}(C_{ZZ})^{-\frac{1}{2}}\exp\left\{-\frac{1}{2}(\bar{z} - Z)^{T}C_{ZZ}^{-1}(\bar{z} - Z)\right\}$$

(8)

1.3. Maximum A Posteriori (MAP) Estimation: Inversion Step

It is reasonable to assume that $n$ is a Gaussian random vector and independent of $z$, $X$ and $e$. Thus, $X$ and $z$ are independent conditional on the knowledge of $Z$. This allows Equation (1) to change as follows:

$$p(Z|X,z) = \frac{p(X|Z)p(z|Z)p(Z)}{p(X|Z)p(z|Z)p(Z)} \propto p(X|Z)p(z|Z)p(Z)$$

(9)

Note that in Equation (9), $p(X, z)$ is a constant. Although this equation is different from Equation (10) in a study by Hardie et al. (2004), they are equivalent. See Appendix A for details.

We begin by deriving the MAP estimation by neglecting the spectral consistency term of $p(z|Z)$ in Equation (10):

$$p(Z|X,z) \propto p(X|Z)p(Z)$$

(10)

Although neglecting the spectral consistency term is unreasonable, we will find that it is what EGIF does from the Bayesian perspective. And Section 2.5 introduces the MAP solution with consideration of the spectral consistency term.

The MAP solution $\hat{Z}$ can be found by minimizing the corresponding objective function $[12,55]$ of Equation (10), $o(Z)$, which can be formed by the exponent terms in Equations (7) and (8):

$$o(Z) = (X - (BZ + a))^{T}C_{e}^{-1}(X - (BZ + a)) + (\bar{z} - Z)^{T}C_{ZZ}^{-1}(\bar{z} - Z)$$

(11)

$\hat{Z}$ can be calculated as:

$$\hat{Z} = \hat{C}[C_{ZZ}^{-1}\bar{z} + B^{T}C_{e}^{-1}(X - a)]$$

(12)

$$\hat{C}^{-1} = C_{ZZ}^{-1} + B^{T}C_{e}^{-1}B$$

(13)
where \( \hat{C} \) is the estimated covariance matrix with \( QN \times QN \) elements, measuring the uncertainty of the \( \hat{Z} \) estimation.

\( C_e \) and \( C_{ZZ} \) can be interpreted as the relative contribution from the observed Pan and MS images. Similar to Fasbender et al. [54], we define a weight parameter \( s \) to adjust their contributions, which we interpret as the weight given to the Pan information at the expense of the MS information. By introducing \( s \), \( C_e \) and \( C_{ZZ} \) are divided by \( 2s \) and \( 2(1-s) \), respectively, as the final covariance matrix. In this way, the best estimation can be given by

\[
\hat{Z} = \hat{C}[2(1-s)C_{Z}^{-1}\hat{z} + 2sB^TC_{e}^{-1}(X-\alpha)]
\]

(14)

\[
\hat{C}^{-1} = 2(1-s)C_{Z}^{-1} + 2sB^T C_{e}^{-1}B
\]

(15)

with a generalized intensity vector, \( \tilde{\gamma} = B\hat{z} + \alpha \), defined as in a study by [25], applying the matrix inversion lemma and simplifying the results yields the following equation:

\[
\hat{Z} = \hat{z} + sC_{Z}B^T[(1-s)C_{e} + sBC_{Z}B^T]^{-1}(X-\tilde{\gamma})
\]

(16)

\( s \) is in a range from 0 to 1. Setting \( s = 0.5 \) lends the same weight to both images. If \( s = 0 \), the results are \( \hat{Z} = \hat{z} \), which are the blurred images obtained by up-sampling the LR MS images. The information from the Pan image is simply neglected in this case.

This solution unfortunately involves many unknown parameters, including a \( QN \times QN \) covariance matrix \( C_{ZZ} \), an \( N \times N \) covariance matrix \( C_e \), an \( N \times QN \) coefficient matrix \( B \) and an \( N \) element coefficient vector \( \alpha \). Thus assumptions must be made about the properties of these random vectors to lower the number of parameters to be estimated and make the problem manageable.

1.4. Extended General Image Fusion (EGIF) Framework

The detail injection methods can be expressed in an EGIF [8,11,13]:

\[
\hat{Z} = \hat{z} + \Omega(X - \tilde{\gamma})
\]

(17)

where \( \Omega \) represents the modulation coefficient matrix with \( QN \times N \) elements. \( \tilde{\gamma} \) represents a vector with the same dimensions as the HR image \( X \), which can be calculated by low-pass filtering image \( X \) according to an MRA method or by combining the LR MS images according to a CS method.

1.5. CS Methods from a Bayesian Perspective

One common assumption in some model-based and CS methods is that the Pan image \( X \) is a linear combination of HR MS images \( Z \) [54,58–66] as in Equation (5). Equation (16) solves for these methods.

To estimate the unknown parameters, we assume that the pixels are spatially independent (Appendix B discusses spatial independence in detail) and share the same variance and regression coefficients, i.e., stationary second-order statistics. The local and global modulation coefficients correspond with the local and global stationarity, respectively:

\[
C_e = \sigma_e I_N \\
\alpha = \alpha I_N \\
B = \text{diag}(\beta, \beta, \ldots, \beta) \\
C_{ZZ} = \text{diag}(C_Q, C_Q, \ldots, C_Q)
\]

(18)
where \( \mathbf{I}_N \) is an identity matrix with \( N \times N \) elements, \( \mathbf{iv} \) is an identity vector with \( N \) elements, \( \mathbf{b} = [\mathbf{b}^1, \mathbf{b}^2, ..., \mathbf{b}^Q] \), \( \mathbf{a}, \mathbf{b}^1, \mathbf{b}^2, ..., \mathbf{b}^Q \) are regression coefficients, \( \mathbf{C}_Q \) is a covariance matrix with \( Q \times Q \) elements to measure the covariance between different spectral bands and \( \sigma_i \) is the variance of the regression residual in the relationship \( g \) seen in Equation (5). These \((Q^2 + Q + 2)\) unknown parameters, \( \mathbf{b}, \mathbf{a}, \mathbf{C}_Q \) and \( \sigma_i \), can be estimated from the observed MS images \( \mathbf{z} \), the intensity image \( \mathbf{y} \) and the degraded Pan image \( \mathbf{x} \). Define an modulation coefficient vector, \( \mathbf{w} = [\omega^1, \omega^2, ..., \omega^Q]^T \), with \( \omega^q \) being the modulation coefficient for the \( q \)th band:

\[
\mathbf{w} = s\mathbf{C}_Q\mathbf{b}^T[(1-s)\mathbf{I}_N + s\mathbf{b}\mathbf{C}_Q\mathbf{b}^T]^{-1}
\tag{19}
\]

The solution Equation (16) has the same formulation as Equation (17) \((\mathbf{Q} = \text{diag}(\mathbf{w}^T, \mathbf{w}^T, ..., \mathbf{w}^T)_N \) with \( \mathbf{w} \) as Equation (19) and follows the general scheme of a CS method \([25]\). This indicates that all CS methods are special cases of this MAP solution that use different information sources \([41, 44, 54]\) but lack of detail explanation. With a parameter \( s \), we found that the IHS, generalized IHS (GIHS) and Brovey transform methods all satisfy this equation. Thus they can be interpreted as special cases of the GS method by neglecting the time-consuming covariance calculation process and redistributing the detail injection among different bands under Equation (20). This also explains why all the comparison studies of the IHS, GIHS, Brown transform and GS methods have found the GS method to be the best in terms of spectral preservation and spatial injection \([2, 7, 25]\).

Previous studies have introduced similar weighting parameters \( s \) to balance the contributions from different information sources \([41, 44, 54]\) but lack of detail explanation. With a parameter \( t \), Choi’s method \([41]\) can be rewritten into the general CS framework by setting}

<table>
<thead>
<tr>
<th>CS</th>
<th>MRA</th>
<th>( \mathbf{w}/\mathbf{w}_0 )</th>
</tr>
</thead>
<tbody>
<tr>
<td>GIHS and IHS</td>
<td>GLP</td>
<td>( \mathbf{w}_0 )</td>
</tr>
<tr>
<td>GS ((s = 1))</td>
<td>GLP-M3 ((s = 0.5))</td>
<td>( [\sigma^1_{Y, Y}/\sigma^{0}<em>{Y, Y}, \sigma^2</em>{Y, Y}/\sigma^{0}<em>{Y, Y}, ..., \sigma^Q</em>{Y, Y}/\sigma^{0}_{Y, Y}]^T ) ((Y = \mathbf{X} \text{ for MRA}))</td>
</tr>
<tr>
<td>Brovey</td>
<td>HPM</td>
<td>( \mathbf{z}/\hat{\mathbf{y}}_n ) ((\hat{\mathbf{y}}_n = \hat{\mathbf{x}} \text{ for MRA}))</td>
</tr>
</tbody>
</table>

We can interpret the IHS and Brovey transformation methods as special cases of the GS method. In the GS method (derived by setting \( s = 1 \)), the relationship between the modulation coefficient vector \( \mathbf{w} = [\sigma^1_{Y, Y}/\sigma^{0}_{Y, Y}, \sigma^2_{Y, Y}/\sigma^{0}_{Y, Y}, ..., \sigma^Q_{Y, Y}/\sigma^{0}_{Y, Y}]^T \) and the regression coefficient vector \( \mathbf{b} \) is:

\[
\mathbf{b}\mathbf{w} = \mathbf{b}\mathbf{C}_Q\mathbf{b}^T[(1-s)\mathbf{I}_N + s\mathbf{b}\mathbf{C}_Q\mathbf{b}^T]^{-1} = 1 - \sum_{q=1}^{Q} \beta^q \omega^q
\tag{20}
\]
\[ \omega = (1 - 1/t) i_q \quad t \geq 1 \] (21)

Tu et al. [44] introduced a parameter \( l \), which can be written into the general CS framework by setting
\[ \omega_n = i_q + (\tilde{z}_n - \tilde{y}_n) / [(l-1)X_n + \tilde{y}_n] \quad l \geq 1 \] (22)

1.6. MRA Methods from a Bayesian Perspective

The MRA method formulations show that estimate of fused MS band \( q \), \( \hat{Z}^q \), is independent of the other MS bands[11,27,67]. Thus, we assume that \( Z^1 \), \( Z^2 \), ..., \( Z^Q \) are all conditionally independent on \( X \), with a mean vector \( \tilde{z}^1 \), \( \tilde{z}^2 \), ..., \( \tilde{z}^Q \) and a covariance matrix \( C_{1z}, C_{2z}, ..., C_{Qz} \). Furthermore, \( Z^q \) and \( X \) are linearly correlated [55–57,67]:
\[ X = g(Z^q) + e^q = B^q Z^q + \alpha^q + e^q \] (23)

where \( \alpha^q \) and \( e^q \) have \( N \) elements, \( B^q \) has \( N \times N \) elements and \( e^q \) has a covariance matrix \( C_e^q \). Thus, the MAP estimate is given by
\[ \hat{Z}^q = \tilde{z}^q + s^q C_{zz}^q (B^q)^T [(1-s^q)C_e^q + s^q B^q C_{zz}^q (B^q)^T]^{-1} (X - \tilde{y}^q) \quad q=1,2,...,Q \] (24)
\[ (C_e^q)^{-1} = 2(1-s^q)C_{zz}^q + 2s^q B^q (B^q)^T (C_e^q)^{-1} B^q \quad q=1,2,...,Q \] (25)

where \( \tilde{y}^q = B^q \tilde{z}^q + \alpha^q \) and \( s^q \) is the weight parameter for the \( q \)th band.

\( X \) has a Gaussian distribution with an unknown mean \( E(X) \) and a covariance \( C_{XX} \) with \( N \times N \) elements as we assume that \( Z \) and \( X \) are linearly correlated and that \( Z \) has a Gaussian distribution. We can similarly assume that \( X \) has an expected value \( E(X) = \tilde{x} \). Furthermore, \( B^q \tilde{z}^q + \alpha^q = \tilde{x} = \tilde{y}^q \), for \( q = 1, 2, \ldots, Q \). Thus,
\[ \hat{Z}^q = \tilde{z}^q + s^q C_{zz}^q (B^q)^T [(1-s^q)C_e^q + s^q B^q C_{zz}^q (B^q)^T]^{-1} (X - \tilde{x}) \quad q=1,2,...,Q \] (26)

where \( B^q = C_{XX} (C_{zz})^{-1} \) and \( C_e^q = C_{XX} - C_{zz} (C_{zz})^{-1} (C_{XX})^T \), with \( C_{zz}^q \) being the covariance matrix between vectors \( Z^q \) and \( X \).

As with the CS methods, assumptions must be made to make the parameters easier to estimate:
\[ C_{zz}^q = \sigma_{zz}^q I_N \]
\[ C_{XX}^q = \sigma_{XX}^q I_N \]
\[ C_{zz} = \sigma_{zz} I_N \] (27)

where \( \sigma_{zz}^q \), \( \sigma_{XX} \) and \( \sigma_{zz} \) are the variance and covariance values for the corresponding covariance matrices. These matrices have only \( 2Q+1 \) unknown parameters and can be estimated from the observed MS images \( z \) and degraded Pan image \( x \). Thus, the modulation coefficient for the \( q \)th band, \( \omega^q \), is:
\[ \omega^q = \frac{s^q \sigma_{zz}^q}{(1-s^q)\sigma_{XX} + (2s^q-1)(\sigma_{zz}^q)^2/\sigma_{zz}^2} = \frac{s^q \sigma_{zz}^q}{(1-s^q)+(2s^q-1)(\rho^q)^2} \] (28)

where \( \rho^q = \sigma_{zz}^q/\sqrt{(\sigma_{zz}^q)^2/\sigma_{XX}} \) represents the correlation coefficient between bands \( X \) and \( Z^q \).

Thus the MRA methods, derived by setting \( \Omega = \text{diag}(\omega^q, \omega^q, \ldots, \omega^q) \) in Equation (17) with \( \omega = [\omega^1, \omega^2, \ldots, \omega^Q] \) and \( \omega^q \) as Equation (28), are special cases of the Bayesian fusion method that uses different \( s^q \) values to weigh the different information sources. Table 1 lists some MRA modulation coefficients derived from different weights. Setting \( \omega^q = 1 \) produces the high-pass filtering method or the simple GLP
method depending on what filtering is used in MRA. Setting \( \omega^q = \bar{Z}/\bar{x} \) gives the HPM method [37], which corresponds to the Brovey method in CS category as \( \bar{x} \) corresponds to \( \bar{y}_n \) deducted above. Setting \( \omega^q = \sigma_{ZX}^q/\sigma_{XX}^q \) produces the M3 modulation coefficient [11,68] corresponding to the GS method in CS category (Table 1).

We can derive the weight from the modulation coefficient,

\[
\sigma^q = \frac{\omega^q[\sigma_{XX} - (\sigma_{ZX}^q)^2 / \sigma_{ZX}^q]}{\sigma_{ZX}^q + \omega^q[\sigma_{XX} - 2(\sigma_{ZX}^q)^2 / \sigma_{ZX}^q]} = \frac{1 - (\rho^q)^2}{\sigma_{ZX}^q / (\omega^q \sigma_{XX}) + 1 - 2(\rho^q)^2}
\]

(29)

From this equation we can derive \( s^q = 0.5 \) from the M3 modulation coefficient, which has the similar formulation with the GS method derived by setting \( s = 1 \) in the CS method (Table 1). Similarly, introducing a new variable, global correlation coefficient \( \rho^q \), we can derive \( s^q = (1 - (\rho^q)^2)/(\rho^q + 1 - 2(\rho^q)^2) \) from the ECB coefficient [27] and \( s^q = (1 - (\rho^q)^2)/(\rho^q + 1 - 2(\rho^q)^2) \) from the AABP coefficient [36].

2. Relationships among Spectral Preservation, Spectral Consistency and Spatial Injection in Pansharpening

2.1. Relationship between the Multi-Resolution Analysis (MRA) and Component Substitution (CS) Methods

From the modeling process in the Bayesian data fusion framework, the difference between the MRA and CS methods lies only in how the HR MS and Pan images are correlated (Equations (5) and (23)). In the modeling process of the CS methods, the linear correlation (Equation (5)) can be seen as a constraint to the Gaussian assumption of the MS images (Equation (8)) as long as the number of MS bands is larger than 1 (i.e., the unknown variables are more than the given variables in Equation (5)). Setting \( s = 1 \) indicates that the Gaussian variables are estimated under this linear correlation constraint, i.e., the GS method. In the MRA methods, the linear correlation assumption (Equation (23)) completely competes with the Gaussian assumption of the MS images (Equation (8)) as we can derive the solution by solely solving Equation (23) (i.e., the unknown variables have the same number with the given variables). Thus, setting \( s = 0.5 \) indicates a good tradeoff between the two assumptions, i.e., the M3 injection model. If the normalized spectral responses are ideal and the linear combination assumption can be satisfied, i.e., \( \sigma_v = 0 \) in Equation (18), then the M3-GLP and GS methods are exactly the same.

The assumption of \( \sigma_v = 0 \) is not realistic, as demonstrated by Thomas et al. [10]. It is even violated when sharpening for newly developed sensors where the Pan and MS spectral bandwidths do not overlap (e.g., the near infrared (NIR) band of SPOT-5, blue band of IKONOS and coastal, and the NIR1 and NIR2 bands of WorldView-2 and the forthcoming WorldView-3) [3], when sharpening MS images with synthetic aperture radar data [69,70] and when sharpening thermal images with visible and NIR images [71]. To minimize \( \sigma_v \) and make the linear combination assumption reasonable, the newly developed CS methods focus on creating an ideal intensity component by accounting for the spectral response functions [29,30,72] or by conducting multiple regression analyses of the degraded Pan image and original MS images [8,25,42]. The multiple-regression-analyses approach harkens back to studies conducted in the 1990s [73,74]. The traditional method for minimizing \( \sigma_v \) is to histogram match the Pan image \( X \) to the linear combination intensity \( \hat{y} \) [25]. Another recently developed approach
involves injecting Pan spatial details into the $\mathbf{y}$ to decrease $\sigma_e$ [32–34,75]. This is referred to as the combined CS/MRA method.

2.2. Degree of Spatial Enhancement

Many studies have observed that the spatial enhancement of CS methods is larger than that of MRA methods [27,40–42]. This is because $X - \mathbf{y}$ in Equation (16) of the CS methods could have more spatial details than $X - \mathbf{x}$ in Equation (26) of the MRA methods as in the CS methods Pan image $X$ cannot be an exactly linear combination of HR MS images $\mathbf{Z}$ (i.e., $\sigma_e$ in Equation (18) cannot be 0 see Section 2.1 and it can add some artificial spatial details into $X - \mathbf{y}$). However, from a Bayesian perspective, spatial enhancement is also controlled by the parameter $s$ and thus the modulation coefficient. In fact, when $s$ is set to 1, for the CS methods, the modulation coefficient $\omega^q$ has a maximum value of $\sigma^q_{Z}/\sigma_{X,Y}$. For the MRA methods, the corresponding counterpart of the GS modulation coefficient is $\sigma^q_{Z}/\sigma_{X,X}$, which can be obtained by setting $s = 0.5$ (Table 1 and Section 1.6). And $\omega^q$ has a maximum value of $\sigma^q_{Z}/\sigma_{X,Z}$. $\sigma^q_{Z}$ (the maximum CS modulation coefficient by setting $s = 1$) $\leq \sigma^q_{Z}/\sigma_{X,X} < \sigma^q_{Z}/\sigma_{X,Z}$ (the maximum MRA modulation coefficient by setting $s^q = 1$). This indicates that the amount of spatial information provided by the MRA methods may be more than that provided by the CS methods when $s^q > 0.5$ in MRA methods. This possibility is verified in the experimental section.

2.3. Are Spatial Injection and Spectral Preservation Competitive?

Many researchers have believed that there is a tradeoff between spatial information injection and spectral information preservation. In fact, the tradeoff between the spatial enhancement and spectral preservation is only true in EGIF [52], where the spectral information is measured by its similarity to the up-sampled MS images $\mathbf{z}$. We define the spectral consistency as the first property of Wald’s protocol [51] that once degraded to its original resolution, any synthetic image $\mathbf{Z}$ should be as identical as possible to the original image $\mathbf{z}$ [52]. This is observed in Equation (2), and is neglected by both the MRA and CS methods in Equation (10).

2.4. Are the Up-Sampled Images Spectrally Consistent?

Usually, the up-sampled images $\mathbf{z}$ and $\mathbf{x}$ are derived using an expansion and a corresponding low-pass expansion filter [28,76]. However, none of the up-sampling methods explicitly satisfies the spectral consistent property, i.e., $\mathbf{Hx} \neq \mathbf{x}$. In fact, the up-sampled images are spectrally consistent only if the sensor PSF is ideal and the nearest neighbor resampling method is applied. Massip et al. [68] recently demonstrated that de-convoluting the MS images according to the sensor PSF before up-sampling could improve the fusion results, which in fact indicates that the assumption $\mathbf{Hx} = \mathbf{x}$ is more reasonable when the sensor PSF is more like ideal after de-convolution.

As $\mathbf{Hx} \neq \mathbf{x}$, the spatial detail is not zero-mean (i.e., $\mathbf{H}(X - \mathbf{x}) = \mathbf{x} - \mathbf{Hx} \neq 0$). Thus the MRA methods cannot fulfill the consistency condition [10,11,52]. Furthermore, applying a non-zero-mean modulation coefficient, which varies as a function of spatial location, exacerbates this problem.
2.5. How to Obtain a Spectrally Consistent Solution

The reason why all of the traditional EGIF methods including MRA methods are not spectrally consistent lies in their neglecting the spectral consistency term \( p(z|Z) \) in Equation (9) from a Bayesian perspective (see Equation 10 and Section 1.3 how we derive the traditional EGIF methods from the Bayesian perspective). The so-called spectral consistency in the EGIF methods is only roughly guaranteed by their assumption that the MS images have a Gaussian distribution with a mean value comprising the up-sampled MS images. This section solves Bayesian Equation (9) with consideration of the spectral consistency term \( p(z|Z) \). The solution of the traditional detail injection methods, i.e., \( p(Z)p(X|Z) \), follows a Gaussian distribution with a mean vector \( \hat{Z} \) in Equation (14) and a covariance matrix \( \hat{C} \) in Equation (15):

\[
p(Z)p(X|Z) \propto \exp\left\{ -\frac{1}{2}(Z - \hat{Z})^T \hat{C}^{-1}(Z - \hat{Z}) \right\}
\]

When incorporating Equation (7) (i.e., the \( p(z|Z) \) term) and Equation (30), the close-form solution for the minimization can be similarly obtained by determining where the gradient of the cost function is zero, as the second derivative is always positive [12,55]:

\[
\hat{S}_Z = (H^T C_n^{-1} H + \hat{C}^{-1})^{-1} (H^T C_n^{-1} z + \hat{C}^{-1} \hat{Z}) = \hat{Z} + \hat{CH}^T (\hat{HC}^T + C_n)^{-1} (z - H\hat{Z})
\]

where \( \hat{S}_Z \) is the spectrally consistent estimation of \( Z \). However, this solution involves the formulation and inversion of a large matrix, \( H\hat{CH}^T + C_n \), with \((QM) \times (QM)\) elements, making it computationally extensive and unable to be solved pixel by pixel as in solving \( \hat{Z} \). To avoid such a process, some previous studies [55,57,58,77–79] have assumed an ideal (rectangular) PSF. In this case, \( H \) is block diagonal and the large equation system in Equation (31) can be spatially decomposed into independent subsets by segmenting the images into blocks. However, the bell-shaped modulation transfer function (MTF) of the real sensor system makes the decomposition impossible.

Although the steepest gradient descent method [59,62,77–79] can be used with an arbitrary sensor PSF to solve Equation (31) without inverting the large matrix, no study has attempted to do so except Eismann and Hardie [60] used the conjugate gradient search algorithm to fuse multispectral and hyperspectral images. As the conjugate gradient search algorithm establishes conjugacy for successive search directions, it can be used to avoid the stagnation that can occur for the steepest gradient search algorithms and make optimization more effective. We use the conjugate gradient search algorithm for our estimation. Define:

\[
A = H^T C_n^{-1} H + \hat{C}^{-1}
\]

\[
b = H^T C_n^{-1} z + \hat{C}^{-1} \hat{Z}
\]

then Equation (31) can be solved by:

\[
AZ - b = 0
\]

Because \( A \) is a real, symmetric and positive-definite matrix, the conjugate gradient search algorithm can be applied and is depicted as the following pseudo-codes.
Algorithm 1. Conjugate gradient search algorithm to avoid large matrix formation

Let $Z(0) = \hat{Z}$ (set the initial solution $Z(0)$ to be the results created by the traditional detail injection methods, $\hat{Z}$)

$r(0) = b - AZ(0)$ (r is a vector with the same dimensions as Z. For example, $r(0) = b - AZ(0) = H^T C_n^e (z - HZ(0))$, where $z - HZ(0)$ is a vector that represents the error of the initial solution $Z(0)$ against the LR image $z$ and $H^T$ represents the expansion of this error vector into the HR dimension)

$p(0) = r(0)$ (p is a vector representing the conjugate direction in which the solution $Z(0)$ should be adjusted)

$k = 0$

repeat

$\alpha(k) = [r^T(k)r(k)]/[p^T(k)Ap(k)]$ (\(\alpha\) is a scalar representing the best step with which solution $Z(k)$ should be adjusted)

$Z(k + 1) = Z(k) + \alpha(k)p(k)$ (adjust the solution $Z(k)$ to be more spectrally consistent)

$r(k + 1) = r(k) - \alpha(k)Ap(k)$ (the following statements are to change the direction $p$ to guarantee conjugacy)

if ($r(k + 1)$ is sufficiently small, e.g., has an average element value smaller than 1E-10 in our work, or $k$ is sufficiently large, e.g., 5 in our work) then exit loop

$\gamma(k) = [r^T(k + 1)r(k + 1)]/[r^T(k)r(k)]$

$p(k + 1) = r(k + 1) + \gamma(k)p(k)$

$k = k + 1$

end repeat

The result is stored in $Z(k+1)$. The sentences in brackets after the algorithm statements explain the actions. This iteration process continually adjusts solution $Z(k)$ to be spectrally consistent with $z$. The maximum iteration is set to be 5 as we have experimentally confirmed that the performance increased with the increasing iteration. However, the increase is little and the performance is stable when the iteration is larger than 5. Fortunately, we can implement the algorithm without forming these matrices/vectors by performing these operations in the image form. Most of the operations in the algorithm are easily implemented in the image domain, as matrices $C_n$ and $\hat{C}$ are diagonal. For example, $C_n u$ (with $u$ being an image vector with $QM$ elements, e.g., $z$) means that each pixel in the $u$ image is multiplied by the corresponding diagonal element. However, there are two complicated operations to change vector dimensions: $H$ and $H^T$. The operation $Hv$ (with $v$ being an image vector with $QN$ elements, e.g., $Z$) is to degrade image $v$ by mimicking the sensor PSF, i.e., a two level ATW filter with a scale ratio $r = 4$ in Equation (3). The most difficult operation is $H^T u$. Considering Equation (3), as $H^T = F_1^T D^T_1 F_2^T D^T_2 = F_1^T D^T_1 F_2^T D^T_2$, $H^T u$ is actually expanding the image $u$ by 2 ($D^T_2$), applying the ATW filter to the expanded image ($F_2$) and reapplying the same expansion ($D^T_1$) and filtering ($F_1$) again. Thus, this conjugate gradient optimization technology does not require the formation, let alone inversion, of the large Hessian matrix $A$.

2.6. Spectral Preservation is Complementary with Spatial Injection

Equation (6) is applied in the traditional detail injection method to roughly guarantee spectral consistency, as it assumes that the HR MS images have a Gaussian distribution, with the up-sampled MS images serving as the mean vector. In contrast, Equation (7) strictly guarantees the spectral consistency. Equation (7) has much more freedom than Equation (6), as its known variables ($z$ with $QM$ elements) are $r^2$ times less than the variables to be estimated ($Z$ with $QN$ elements). And only using Equation (7) to estimate $Z$ is an ill-posed problem [53]. Thus, we can expect that rather than
competitive with the spatial detail injection, as the term Equation (6) did in the traditional detail injection methods, this new spectral preservation term is complementary to the spatial detail injection.

3. Experimental Confirmation

To experimentally confirm our previous analysis, we compared the GLP method coupled with two different injection models (i.e., M3 and ECB) representing the MRA category and the GS method representing the CS category. There are many other MRA methods in the literatures [80–83], such as wavelet filter banks [80,81], which may have similar performance of the GLP method in terms of spectral preservation as opposed to Wald’s spectral consistency. The GLP-M3 method was implemented by setting different $s$ values to examine its spatial enhancement capability. To examine the relationship between the spatial enhancement and spectral preservation, we also incorporated the traditional detail injection methods with the spectral consistency constraint of Equation (2) as described in Section 2.5. We named these methods GS-S, GLP-M3-S and GLP-ECB-S, respectively, with “S” representing the spectral consistency. We omitted “GLP” from the names in the following analysis without ambiguity, e.g., “M3” refers to “GLP-M3.”

We implemented GS by computing the simulated LR Pan image as the pixel average of the MS bands, and performed histogram matching using the linear transformation method. The slope of the linear function was the ratio of the standard variances between the LR image $x$ and the intensity image $y$. The intercept of the linear function was set to make the line pass through the point (mean($x$), mean($y$)), where “mean” refers to the average of all of the vector elements. Following [28], in all of the cases involving the GS method, $\tilde{z}$ and $\tilde{x}$ were up-sampled using an expansion and a corresponding low-pass expansion filter, i.e., a 23-taps filter. We also included the plain expansion of the MS dataset, $\tilde{z}$, for comparison, which we referred to as “EXP”. The conjugate gradient search was run for 5 iterations to secure a robust estimation. The ECB was the only local-adaptive injection model. Its coefficients were calculated on a square sliding window of 13 × 13 pixels in size, centered on the pixel in question in the up-sampled images $\tilde{z}$ and $\tilde{x}$ [27] and clipped above 3 and below 0 to avoid numerical instabilities. In this study the 13 × 13 pixel window was used as sensitivity analysis undertaken using different window sizes on our test data did not reveal much difference for windows with 11 to 15 pixel side dimensions. Similar window size of 11 × 11 was utilized in Aiazzi et al. [7].

3.1. Experimental Data

We conducted experiments using two datasets acquired by the QuickBird and WorldView-2 satellites. The selected QuickBird data, with 0.6-m Pan and 2.4-m MS images, consisted of a forest landscape bisected by a broad road near Boulder City, Colorado, U.S. (Figure 1). The MS image consisted of four bands, including R, G, B and NIR. The MS image was 600 × 600 pixels in size with a 2.4-m spatial resolution. The WorldView-2, which simultaneously collects Pan imagery at 0.46 m and MS imagery at 1.84 m, was the first commercial HR satellite to provide eight spectral sensors in the visible NIR range. Due to U.S. government licensing, the imagery information is made commercially available at 0.5 m and 2.0 m. In our dataset, the MS image was 800 × 800 pixels in size with a 2.0-m spatial resolution. We divided the eight MS bands into two groups for testing according to their bandwidth relationship with the Pan band (Figure 2). The first group contained bands 3 (green), 4
(yellow), 5 (red) and 6 (red edge), which were all covered by the Pan band wavelength. For the second group, we selected bands 1 (coastal), 2 (blue), 7 (NIR1) and 8 (NIR2), which were either not covered or not fully covered by the Pan band wavelength. The WorldView-2 scene subset, which contained many complex urban buildings and vegetation across San Francisco, was observed on 9 October 2011 (Figure 1). DigitalGlobe released the data through the 2012 IEEE GRSS Data Fusion Contest.

**Figure 1.** Color compositions of (a) the original QuickBird MS image (2.4 m) at 600 × 600 pixels combined from red, green and blue bands and (b) the original WorldView-2 MS image (2.0 m) at 800 × 800 pixels combined from green, red and red edge bands. The degraded Pan images for (c) QuickBird at 2.4 m and (d) WorldView-2 at 2.0 m.

3.2. Validation Strategies

We conducted pan-sharpening at both reduced and full scales. At the reduced scale, we degraded the Pan and MS images by four before fusion so that we could use the original MS data as references for the fusion result evaluation. We applied a low-pass filter to the HR data, decimated the filtered images by two along both directions, reapplied the same filter and decimated the images again by two. We used 23-taps and ATW low-pass filters on the Pan and MS images, respectively [27,28] to match the MTF of the bands. At the full scale, we directly pansharpened the original MS images using the original Pan image and thus no MS reference images were used for the fusion results evaluation.

The consistency property of the Wald’s protocol, the synthesis property of the Wald’s protocol and Alparone’s protocol without reference were adopted as the validation strategies. To check the consistency property of the Wald’s protocol, we degraded all of the fused products to the original MS resolution by mimicking the sensor PSF [52]. We then evaluated the degraded fused MS product against the original reference MS images. This validation can be applied to both the reduced and full scale experiments. To check the synthesis property of the Wald’s protocol, we need the reference HR MS images and thus can only be applied to the reduced scale experiments. To check the Alparone’s protocol, we do not need the reference HR MS images and thus can be applied to the full scale experiments. Obviously, with reference available, the validation procedure of the consistency and synthesis properties of the Wald’s protocol is very accurate. However, the consistency property is just a necessary condition but not a sufficient condition to guarantee the fused image quality. And the synthesis property is founded on the hypothesis of invariance between scales, which is not always fulfilled in practice [51]. As such validation using Alparone’s protocol without reference is still necessary. Furthermore, a visual comparison is a mandatory step to appreciate the quality of the fused images.
If there are reference images in validation as in checking the consistency and synthesis properties of the Wald’s protocol, four quality indices can be adopted. (1) The first is the ERGAS index, from its French name “relative dimensionless global error in synthesis,” which calculates the amount of spectral distortion [84]. The best ERGAS value is zero; (2) The second is the Q4 index proposed by [85], which is an extension of the universal quality index (i.e., $Q$) suitable for four-band MS images. This index is sensitive to both correlation loss and spectral distortion between two MS images, and allows both spectral and spectral distortions to be combined in a unique parameter. The best value is one, with a range from zero to one. In our experiments, we calculated Q4 on 32 × 32 blocks; (3) The third is the spectral angle mapper (SAM), which calculates the angle between two spectral vectors to estimate the similarities between two different images. The best value is zero. (4) The last is signal to noise ratio (SNR, [86]) in decibel (dB). It is used to measure the ratio between information and noise of the fused image.

If there are no reference images in validation as in checking Alparone’s protocol, three following different quality indices can be adopted. (1) A spectral distortion index, $D_s$, is derived from the difference of inter-band $Q$ values calculated from the fused MS bands and from the original LR MS bands; (2) A spatial distortion index, $D_s$, is derived from the difference of inter-band $Q$ values calculated between the fused MS bands and HR Pan band and between the original LR MS bands and the degraded Pan band; (3) QNR (i.e., Quality with No Reference) is a combination of the preceding spectral/spatial distortion index [87]. They all take values in [0, 1], with zero being the best value for $D_s$ and $D_s$, and one being the best value for QNR.

### 3.3. Experimental Results

Figures 3–5 show the fusion results of different pansharpening methods for the QuickBird and WorldView-2 datasets at the reduced scale. The quantitative evaluation indices are reported in Tables 2–13, which checked the synthesis property of the Wald’s protocol at the reduced scale (Tables 2, 6 and 10), the consistency property of the Wald’s protocol at both the reduced and full scale (Tables 3, 5, 7, 9, 11 and 13) and Alparone’s protocol without reference at the full scale (Tables 4, 8 and 12).

#### Table 2. Quantitative comparison of the fusion results to check the synthesis property of the Wald’s protocol for the QuickBird dataset at the reduced scale, i.e., at 2.4 m. The best result in each row is displayed in bold, and the second best is displayed in italics. The shaded gray cells are for alternative group columns with different categories.

3.3.1. Degree of Spatial Enhancement

The GLP-based methods (e.g., the GLP-M3 method) could exhibit better spatial enhancement than the GS method when the $s$ value was adjusted properly. In all of these figures, when $s$ is set to be larger than 0.75, the spatial enhancement of the MRA methods is larger than that of the GS method (Figures 3–5).

3.3.2. Are the Up-Sampled Images Spectrally Consistent?

None of the up-sampled images found to be strictly spectrally consistent from both the quantitative measurements and visual comparisons. The consistency quantitative matrices of the up-sampled images were shown in the first columns of Tables 3, 5, 7, 9, 11 and 13 (3, 7 and 11 for the reduced scale, and 5, 9 and 13 for the full scale). The ERGAS values are around 1, which is not close to 0. In Figures 3–5, we can also see that the up-sampled images have larger spectral distortions than the MRA fused images as opposed to the reference images, e.g., the roofs in Figures 3 and 4 and the vegetation in Figure 5.

None of the MRA methods actually satisfied the spectral consistency property (Tables 3, 5, 7, 9, 11 and 13). However, the spectral consistency performance of the GLP-based methods was always better than that of the GS method even when the $s$ value increased from 0.5 to 0.75 and 0.9 for the M3 method to gain more spatial enhancement. This indicated that although the GLP-based methods were not spectrally consistent by design, their spectral inconsistency was not as obvious as that of the GS method. That is why so many studies have stated that GLP-based methods perform better in terms of spectral preservation.

3.3.3. Spectral Preservation is Complementary with Spatial Injection

All of the fused images at both the reduced and full scales were almost perfectly spectrally consistent with the LR MS images by adding the spectral consistency constraint (Tables 3, 5, 7, 9, 11 and 13). They all had Q4 values close to 1, big SNR values, and very small ERGAS and SAM values when checking the consistency property at their LR resolutions [52]. The fused products under the spectral consistency constraint also had better quantitative evaluation indices when checking the synthesis property (Tables 2, 6 and 10) and checking Alparone’s protocol (Tables 4, 8 and 12). This improvement was obvious given the respective one-unit decrease in ERGAS and SAM values for the GLP-based methods (Tables 2, 6 and 10). The improvement was even more obvious for the GS method, which made GS-S the second best performance for the QuickBird and WorldView-2 group 2 datasets. The performance increases were also obvious visually. For example, the tone in Figure 3d (GS-S) is...
closer to the observed reference scene than that in Figure 3c (GS). However, there is a case for the WorldView-2 group 1 dataset (Table 8) that the ECB method with spectral consistency constraint showed no improvement in terms of QNR metric. This is possibly because that the QNR at the full scale is not as reliable as the other metrics used at the reduced scale [88] or because that the spatial independence assumptions is violated in the HR dataset.

Furthermore, we found only a negligible decrease in spatial enhancement after making the fused products spectrally consistent (Figures 3–5). This indicated that spectral consistency, which is quite different from spectral preservation to the up-sampled MS images, is complementary with spatial enhancement rather than competitive. For example, comparing the GS-S and GS methods, the sharpness was only slightly weakened (Figures 3–5e and f). Moreover the GS-S method performed very closely to the M3-S method, which indicated that the proposed spectral consistency model was quite effective for making up for the spectral distortion caused by the fusion method.
Figure 3. True color display of the fused results from different strategies for the QuickBird dataset at the reduced scale. Figure 5. Cont.
3.4. Discussions

The Bayesian perspective of the pansharpening methods can be supported by the GS performance dependence of the linear fitness of Equation (5) in our experimental results, i.e., the Pan approximation by the linear MS combination. As basic assumption of the GS method is the perfect linear relationship between the Pan band and MS bands, its performance may be largely affected by the fitness of this linear relationship. As shown in Table 14, the residual variance of the linear regression in Equations (5) and (18) for the WorldView-2 group 2 dataset is much larger (indicating worse representation of Equation 5) than that for the QuickBird and WorldView-2 group 1 datasets. Thus the
GS method performed much worse for the WorldView-2 group 2 dataset than the other two datasets. Researchers have tried to make the regression residual as small as possible, such as via histogram matching in the original CS methods and via injecting spatial details into the linear combination results in the combined CS/MRA method [34].

Table 14. The variance of the regression residual $\sigma_e$ in Equation (18), the modulation coefficient $\omega^q$ in Equation (19) for the GS method and the weight parameter $s^q$ in Equation (29) averaged over the image for the ECB method for the reduced scale experiments. Their average values over all the four bands are shown in the last column.

<td>0.613</td>
</tr>
</tbody>
</table>

The Bayesian perspective of the pansharpening methods can also be supported by confirming the relationship between regression and modulation coefficients of the CS methods (i.e., Equation (20)). For the GS method, because the regression coefficient in Equation (18), $\beta^q$, equals 1/4, the average modulation coefficient ($\omega^q$) value shown in Table 14 is actually $\sum \beta^q \omega^q$. They are all equal to 1, which satisfies Equation (20).

The $s$ value is important as it controls the amount of modulation coefficient and thus the spatial enhancement degree. Theoretically setting $s = 0.5$ would get the best results as there is no prior information on the priority between the linear correlation assumption and the Gaussian distribution assumption. Thus when setting $s = 0.5$ the modulation coefficients were automatically and precisely controlled by the variance and covariance values in Equation (28). However, we could not estimate the variance and covariance properly due to the scale effect [18,87]. As such, the best $s$ value should also compensate the scale effect which is hard to predict [51] and thus requires further research. For example, in our experiments, the best $s$ value was not 0.5. Increasing $s$ from 0.5 to 0.75, i.e., from M3 ($s = 0.5$) and ECB ($s \approx 0.6$) to M3 with $s = 0.75$, resulted in some increase in the algorithm performance for all of the WorldView-2 datasets (The $s$ values for the ECB method were spatially adaptive, with averages around 0.6, as shown in Table 14.)

The Bayesian perspective of the pansharpening methods can also be supported by that experimentally the best $s$ value is 0.5 when there is no scale effect in calculating variance and covariance. Figure 6 shows ERGAS, SAM and Q4 as functions of the $s$ value in the GLP-based methods for the three datasets at the reduced scale. The coefficients were calculated based on the HR images to avoid the scale effect, which was not available in practice. Without exception, the best ERGAS, SAM and Q4 values were achieved by setting $s = 0.5$. 
3.5. Computational Complexity

The last rows of Tables 4, 8 and 12 show the computational times of each algorithm in the full scale experiments. We used an Intel® Dual-Core™ i5 CPU with installed memory of 4.00 GB and a 32-bit Windows 7 operating system as the computer platform in the experiment. All of the codes were written in Matlab language.

The efficiency of the conjugate gradient search to guarantee the spectral consistency was acceptable in the computing environment for an LR MS image around 800 × 800 pixels in size. And it can be improved using recently developed parallel computing paradigm [89]. The algorithm efficiency was proportional to the product of the LR MS pixel number and the spectral band number (i.e., $M \times Q$). This means that when the study area was increased, the computation time increased linearly along with the number of pixels. Compared with the ECB method, the main computational time of the ECB-S method was spent on the conjugate gradient search, as they required the same amount of time to calculate the modulation coefficients. Most of the time spent by the algorithms with the spectral consistency constraint was spent on the conjugate gradient search. The MRA methods with spatial varying modulation coefficients, e.g., ECB, required more time for calculation than the global modulation coefficients, e.g., M3.

4. Conclusions

Despite continuous improvements in the pansharpening algorithm performance, many questions have arisen over the last decade. For example, is the spatial enhancement of CS methods better than MRA methods? Is there a tradeoff between spectral preservation and spatial enhancement in the fused product? What is the difference between the spectral preservation of up-sampled MS images and the spectral consistency against original MS images?

By analyzing the solution of the Bayesian data fusion framework, we found that both CS and MRA methods are special cases of Bayesian data fusion by assuming/modeling (1) the Gaussian distribution of the desirable MS images with the up-sampled MS images comprising the mean value to preserve spectral information and (2) the linear correlation between the MS and Pan bands to inject spatial
information. We derived the established EGIF with different injection models by setting different weight parameters to control the different assumption/model contributions.

The only difference between the CS and MRA methods is how the MS and Pan images are linearly correlated. By adjusting weight parameters to balance the spectral preservation and spatial injection, the MRA methods can perform better than the CS methods in terms of spatial injection. The experimental results related to two images captured by QuickBird and WorldView-2 satellites confirmed this conclusion.

It is widely believed that building these two assumptions/models into the detail injection pansharpening framework results in a tradeoff of spatial and spectral quality in the fused product. However, this conclusion comes from an implicit and improper assumption that the up-sampled MS images best preserve the spectral information. The spectral consistency should be defined as that any synthetic image should be as identical as possible to the original image once degraded to its original resolution with regard to sensor PSF. The up-sampled MS images are actually not spectral consistent. And the spectral consistency is guaranteed by incorporating a third model, the spectral consistency model, in the Bayesian data fusion framework. In this way, the spectral consistency constraint should be complementary with spatial injection rather than competitive. Spectrally consistent images with arbitrary sensor PSF can be estimated using the conjugate gradient search method at the expense of computational efficiency. The experimental results confirmed our analysis and found that the performance of the traditional EGIF methods improved significantly after adding the spectral consistency constraint.

The assumptions of the Gaussian distribution of the data and the spatial independence (Appendix B) in the Bayesian method deduction might not be practical in some cases. Future research may attempt to segment the image into regions to make the assumptions more reasonable in each region rather than in the whole image. Alternative solutions are to make a non-Gaussian distribution assumption and to consider the spatial correlation as did in the co-kriging downscaling method [90,91], which may need more complicated optimization techniques to solve the models.

Acknowledgments

This research was supported in part by the National Natural Science Foundation of China through grant number 41371417 and in part by the Hong Kong Research Grant Council through grant number CUHK 444612. We would like to thank DigitalGlobe Inc. for providing the WorldView-2 images through the 2012 IEEE GRSS Data Fusion Contest. Special thanks are due to Luciano Alparone from the Institute of Applied Physics “Nello Carrara” CNR Area di Ricerca di Firenze (IFAC-CNR), Italy, for his invaluable recommendations in relation to the experimental simulations. We would like to thank anonymous reviewers for valuable comments and suggestions.

Author Contributions

Hankui Zhang proposed the research framework, performed the experiments and wrote the first draft of the paper. Bo Huang helped to conceive and design the experiments, and contributed to the manuscript preparation and revision.

Conflicts of Interest

The authors declare no conflict of interest.
Appendix

A. The Relationship between this Bayesian Solution and Previous Solutions

Although the deduction process for the Bayesian estimation may be different from those of Hardie et al. [55] and Fasbender et al. [54], they are more consistent than conflicting. We illustrate their consistencies in the following analysis.

Equation (9) is exactly Equation (8) in the study by Hardie et al. [55]. Although \( p(Z) \) in Equation (9) is cancelled out in Equation (10) in the study by Hardie et al. [55], there is no conflict between them, as

\[
p(Z \mid X, z) = \frac{p(X \mid Z) p(z \mid Z) p(Z)}{p(X, z)} \propto p(X \mid Z) p(z \mid Z) p(Z) \propto p(Z \mid X) p(z \mid Z) \tag{A-1}
\]

Note the difference between \( p(X \mid Z) \) and \( p(Z \mid X) \), which determines whether \( p(Z) \) should be cancelled. Setting \( s = 0.5 \) in Equations (24) and (25) results in the same solution as that seen in the study by Hardie et al. [55]. When \( p(z \mid Z) \) is neglected, our solution is:

\[
\hat{Z}^q = \hat{z}^q + C_{Z,X}^v (B^v)^T [C_{e}^v + B^v C_{Z,X}^v (B^v)^T]^{-1} (X - \bar{x}) = \check{z}^q + C_{Z,X}^v (X - \bar{x}) \quad q = 1, 2, ..., Q \tag{A-2}
\]

which is exactly the same as Equation (13) in the study by Hardie et al. [55] with \( p(z \mid Z) \) neglected. When we consider \( p(z \mid Z) \), our solution is Equation (31), which is exactly the same as Equation (20) in the study by Hardie et al. [55].

Equation (9) is exactly the same as Equation (2) in the study by Fasbender et al. [54], with \( p(Z) \) neglected. However, according to their assumption (1) in Section III.B, \( p(z \mid Z) \) has the same formulation as \( p(Z) \) in our assumption, i.e., \( \text{“Z is a Gaussian vector with mean vector } \bar{z} \text{ and covariance matrix } C_{ZZ} \). Thus, the solution obtained by Fasbender et al. [54] in the equations at the end of Section III is exactly the same as our solution when \( p(z \mid Z) \) is neglected, i.e., Equations (14), (15) and (16).

B. The Meaning of Spatial Independence

The desirable HR MS images \( Z \) are assumed to be spatially independent with a mean vector \( \bar{z} \) and a covariance matrix \( C_{ZZ} \). This assumption seems absurd due to the existence of spatial autocorrelation. However, it only indicates that the residual variable \( (Z - \bar{z}) \) is spatially independent with a mean vector \( 0 \) and a covariance matrix \( C_{ZZ} \). Although \( Z \) is a spatially correlated variable, the misusing \( \bar{z} \) operation spatially decorrelates the pixels as the spatially varying mean vector \( \bar{z} \) captures most of the spatial correlation [57]. This kind of spatial independence does not oppose the spatial correlation in the simple kriging method, in which \( Z \) is a spatially correlated variable with a constant mean for the entire image and a spatially correlated covariance matrix. Similarly, the regression residual \( e \) in Equation (5) and \( e^q \) (not the variable \( X \)) in Equation (23) can be assumed to be spatially independent, as most of the spatial correlation is explained by the equation \( g(Z) \) with a spatially correlated variable \( Z \).
