All the stabilizer codes of distance 3

Sixia Yu, Juergen Bierbrauer, Ying Dong, Qing Chen, and C.H. Oh

Abstract—We give necessary and sufficient conditions for the existence of stabilizer codes \([n,k,d]\) of distance 3 for qubits: 

\[ n-k \geq \left\lceil \log_2(3n+1) \right\rceil + \epsilon_n \]

or 

\[ n = 2^{m+2}+1 - \{1,2,3\} \]

for some integer \(m \geq 1\) and \(\epsilon_n = 0\) otherwise. Or equivalently, a code \([n,n-r,3]\) exists if and only if 

\[ n \leq (4^r - 1)/3 \]

for even \(r\) and 

\[ n \leq 8(4^{r-3} - 1)/3 \]

for odd \(r\). Given an arbitrary length \(n\) we present an explicit construction for an optimal quantum stabilizer code of distance 3 that saturates the above bound.

Index Terms—quantum error correction, 1-error correcting stabilizer codes, quantum Hamming bound, optimal codes

I. INTRODUCTION

Quantum error-correcting codes [2], [13], [17], [19] provide us an active way of protecting our precious quantum data from quantum noise and play an essential role in various quantum informational processes. Simply speaking, a QECC is just a subspace that corrects types of errors. When the subspace is specified by the joint +1 eigenspace of a group of commuting multilocal Pauli operators, i.e., direct products of local Pauli operators, the codes are called stabilizer codes [6], [7], [9]. We consider only binary codes here. As usual we denote by \([n,k,d]\) a stabilizer code of length \(n\) and distance \(d\), i.e., correcting up to \([d-1]/2\) qubit errors, that encodes \(k\) logical qubits. The redundancy \(r = n-k\) counts the number of the independent generators of the stabilizer.

One fundamental task is to construct optimal codes, e.g., codes with largest possible \(k\) with fixed \(n\) and \(d\). In the case of \(d = 2\) all optimal stabilizer codes are known. In the simplest nontrivial case \(d = 3\), a systematic construction for all lengths has not been achieved yet. Known results include Gottesman’s optimal codes family [10] of lengths \(2^m\) with \(m \geq 3\) which has been generalized for even lengths [14] by using Steane’s enlargement construction [20] with some codes being optimal and some are suboptimal, i.e., one logical qubit less than the quantum Hamming bound.

A code of distance \(d\) is degenerate if there are harmless undetectable errors acting on less than \(d\) qubits, i.e., errors can not be detected but do not affect the encoded quantum data. If all errors acting on less than \(d\) qubits can be detected, the codes are non-degenerate or pure. For a pure code of distance 3 all errors that occurred on at most 2 qubits can be detected. The quantum Hamming bound (qHB), e.g.,

\[ r \geq s_H = \left\lceil \log_2(3n+1) \right\rceil \]

for a stabilizer code \([n,n-r,3]\), had been proven initially for non-degenerate codes. It is also valid for degenerate codes of distances 3 and \(5\) [9] and of a large enough length as shown in [1] via the linear programming (LP) bound [7], [15]. Our main result reads

**Theorem 1** Let \(f_m = (4^m - 1)/3\). A stabilizer code \([n,n-r,3]\) exists if and only if

\[ r \geq s_H + \epsilon_n \]

where \(\epsilon_n = 1\) if \(n = 8f_m + \{1,2\}\) or \(n = f_m+2 - \{1,2,3\}\) for some integer \(m \geq 1\) and \(\epsilon_n = 0\) otherwise (equivalently: 

\[ n \leq f_{r/2}, f_{r/2} - n \notin \{1,2,3\} \]

for even \(r\), 

\[ n \leq 8f_{(r-3)/2}, n \neq 8f_{(r-3)/2} - 1 \]

for odd \(r\)).

For the definition of quantum stabilizer codes see [6], [7]. The translation into the language of finite geometries is in [4], see also the manuscript [8]. Here the Pauli matrices are identified with the binary pairs, \(\{I,X,Y,Z\} = \mathbb{F}_2^4\), and an \([n,n-r]\) quantum code is described by a check matrix of the stabilizer. The defining condition is that any two generators are orthogonal with respect to the symplectic inner product. Each of the \(n\) qubits corresponds to a pair of columns of the check matrix. Each column is a binary \(r\)-tuple. The nonzero tuples are identified with the points of the \((r-1)\)-dimensional binary projective space: \(\mathbb{F}_2^{r} \setminus \{0\} = PG(r-1,2)\). In this setting the stabilizer is described by a family of \(n\) lines in \(PG(r-1,2)\).

After introducing some notation and recalling known results essential to our construction in Sec.II, we shall present a general construction for optimal codes of arbitrary length \(n > 38\) that saturates the bound Eq.(2) in Sec.III. In Sec.IV we shall prove the only if part by showing that the qHB cannot be attained when \(\epsilon_n = 1\). In Sec. V we shall provide explicitly some of the pure optimal codes of lengths \(n < 38\), which are essential to our general construction, using a generalization of the code pasting method.

II. NOTATIONS AND KNOWN RESULTS

Our construction is based on two families of pure codes and Gottesman’s stabilizer pasting [11] to build new codes from old pure codes. As usual we denote by \(X,Y,Z\) the Pauli operators and by \(I\) the identity operator. Furthermore we write \(X(n) = X_1X_2\cdots X_n\) where \(X_i\) is the Pauli operator \(X\) acting nontrivially on the \(i\)-th qubit only and use analogous expressions for \(Y(n), Z(n)\), and \(I(n)\). For simplicity we shall denote by \([n,r]\) the stabilizer of a pure stabilizer code.
whose stabilizer reads
\[
\begin{array}{cccccc}
X & X & X & X & I \\
Z & Z & Z & Z & I \\
Y & X & Z & I & X \\
Y & Z & X & I & Z \\
\end{array}
\quad (3)
\]

where a juxtaposition of some Pauli operators in the same row means their direct product.

**Codes family** \([2^m] \quad (m \geq 3)\). The first family of codes is the Gottesman family of optimal codes \([2^m, 2^m-m-2, 3] \) with \(m \geq 3\) that saturate the quantum Hamming bound \([10]\).

In the geometric setting this is equivalent to the observation that the points in \(PG(r-1, 2)\) outside a subspace \(PG(r-3, 2)\) can be partitioned into lines. In Ref.\([4]\) this is referred to as the Blokhuis-Brouwer construction \([3]\). By construction, these codes are non-degenerate and two observables \(X(2^m) = X_1 \ldots X_{2^m}\) and \(Z(2^m) = Z_1 \ldots Z_{2^m}\) are generators of the stabilizer. For simplicity we denote by \([2^m]\) a set of \(m+2\) generators of the stabilizer of Gottesman’s code, the first two generators being \(X(2^m) \) and \(Z(2^m)\).

An explicit construction of the remaining \(m\) generators is given by the check matrix \(H_m|A_mH_m\) where \(H_m = [c_0, c_1, \ldots, c_{2^m-1}]\) with the \((k+1)\)-th column \(c_k\) being the binary vector representing integer \(k = 0, 1, \ldots, 2^m-1\) and \(A_m\) is any invertible and fixed point free \(m \times m\) matrix, i.e., \(A_m s \neq 0\) and \(A_m s \neq s\) for all \(s \in F_m^3\). As an example, the unique code \([2^3]\) has a stabilizer generated by
\[
\begin{array}{cccccccc}
X & X & X & X & X & X & X & X \\
I & Z & I & Z & Y & X & Y & X \\
I & Z & Y & Z & X & Z & I & Y \\
\end{array}
\quad (4)
\]

**Codes family** \([8 \cdot m] \quad (m \geq 3)\). The second family of codes are of parameters \([8m, 8m-l_m-5, 3]\) with \(l_m = \lceil \log_2 m \rceil\) as constructed in Ref.\([14]\). One crucial property of this family is that they are stabilized by all \(X\) and all \(Z\) observables \(X(8m)\) and \(Z(8m)\). Here we shall provide a different construction based on Gottesman’s family.

We divide \(8m\) qubits into \(m\) blocks of 8-qubit. The first five stabilizers of the code are \([2^3]m\) whose first two generators are \(X(8m)\) and \(Z(8m)\). In the case of \(m = 3, 4\) the codes are defined in Table I. In the case of \(m \geq 5\) so that \(l_m \geq 3\), the remaining \(l_m\) generators of the stabilizer are obtained from Gottesman’s code \([2^m]\) by replacing the first two generators and then removing arbitrary \(2^m - m\) qubits and finally replacing each single-qubit Pauli operators \(X, Y,\) and \(Z\) in the remaining stabilizers by the corresponding \(8\)-qubit operators \(X(2^3), Y(2^3),\) and \(Z(2^3)\) respectively. In Table I we also present an example in the case \(m = 6\).

A subcode of Gottesman’s code \([2^m]\) and therefore detect all 2 errors in different blocks. Thus all 2-errors can be detected so that we have constructed a pure 1-error-correcting code of length \(8m\).

We shall abuse the notation slightly to denote all the codes of this family by \([8 \cdot m]\) though some of them are not optimal. In fact when \(r+1 \leq m \leq 2^{r+1} - 1\) and \(2^{r+1} - 1 \leq m \leq 2^r\) with \(r \geq 1\), the code \([8 \cdot m]\) is optimal since \(l_m + 5 = s_H\) in these cases. Otherwise the code is suboptimal, i.e., \(l_m + 5 = s_H + 1\).

**Stabilizer pasting** (Gottesman\([11]\)). In the geometric setting stabilizer pasting was rediscovered in Ref.\([4]\) as the generalized Blokhuis-Brouwer construction.

Given two non-degenerate stabilizer codes \([n_2, s_2] = (S_1, S_2, \ldots, S_{s_2})\) and \([n_1, s_1] = (T_1, T_2, \ldots, T_{s_1})\) of distance \(3\), if two observables \(X(n_2)\) and \(Z(n_2)\) belong to \([n_2, s_2]\), say, \(S_1 = X(n_2)\) and \(S_2 = Z(n_2)\), then the stabilizer defined in Table II defines a non-degenerate stabilizer code \([n_2 + n_1, s]\) with \(s = \max\{s_2, s_1 + 2\}\), denoted as \([n_2, s_2] \triangleright [n_1, s_1]\).

As a first example of stabilizer pasting we obtain an optimal code \([13] = ([13, 7, 3])\) by pasting the optimal code \([2^3]\) of length \(n_2 = 8\) and \(s_2 = 5\) stabilizers with the perfect code \([5]\), i.e., \(n_1 = 5\) and \(s_1 = 4\). The resulting code is of length \(n_1 + n_2 = 13\) with \(s_1 + 2 = 6 > s_2 = 5\) stabilizers.

If there is a third pure code \([n_3, s_3]\) with \(X(n_3)\) and \(Z(n_3)\) belonging to its stabilizer then the stabilizer pasting results in a pure code
\[
[n_1 + n_2 + n_3, s] = [n_3, s_3] \triangleright [n_2, s_2] \triangleright [n_1, s_1] \quad (5)
\]
The stabilizers of the pure optimal codes $[[n,n-r,3]]$ for $n \leq 38$ and $n \neq 6$. All the $2\epsilon$-error-detecting blocks such as $[28,7]_2$ are constructed in Sec. V explicitly.

\[\begin{array}{c|c|c}
 n & m & \text{Stabilizer} \\
\hline
 10 & 6 & \text{Table VI} \\
 11 & 6 \{10,6\} & [1,1] \\
 12 & 6 \{10,6\}_2 & [2,4,2] \\
 13 & 6 \{10,6\}_2 & [3,4,2] \\
 14 & 6 \{10,6\}_2 & [4,4,1] \\
 17 & 6 \text{Eq. (5)} & [8] \\
 31 & 7 \{28,7\}_2 & [3,4,2] \\
 32 & 7 [2^k] & [3,8] \\
 33 & 7 \{28,7\}_2 & [5,5,2] \\
 34 & 7 \{28,7\}_2 & [7,5,1] \\
 35 & 7 \{28,7\}_2 & [7,7,1] \\
 36 & 7 \{28,7\}_2 & [7,5,1] \\
 38 & 7 \text{Eq. (11)} & [7] \\
\end{array}\]

A direct application of stabilizer pasting to two optimal codes yields an optimal pure code $[[37,30,3]]$ whose stabilizer reads $[37] = [2^3] [5]$.

The following construction of an optimal pure code $[38] = [[38,31,3]]$ is translated from the geometric construction in Ref. [4]. We denote by $H_{32} = [H_{26}, A, B]$ a $5 \times 2^5$ matrix whose columns $h_i$ are all possible 5-dimensional vector with entries $0, 1$ where $A, B$ are two $5 \times 3$ matrices

\[ A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}. \]

Also we denote by $H'_{32} = [H'_{26}, A', B'] = E_1 + MH'_{32}$ which is another $5 \times 2^5$ matrix, where

\[ E_1 = \begin{pmatrix} 1_{32} \\ 0_{32} \\ 0_{32} \\ 0_{32} \\ 0_{32} \end{pmatrix}, \quad M = \begin{pmatrix} 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 1 & 1 & 0 & 1 \end{pmatrix}. \]

Both $M$ and $I + M$ are invertible. Furthermore we denote

\[ [P|Q] = \begin{pmatrix} 1_{26} & 1_{3} & 1_{3} & 0_{6} & 1_{26} & 1_{3} & 1_{3} & 0_{6} \\ 0_{26} & 0_{3} & 1_{3} & 0_{6} & 1_{26} & 0_{3} & 1_{3} & 0_{6} \end{pmatrix}. \]

The check matrix of the stabilizer $[38]$ reads

\[ H_{26} A A' P A'' H'_{26} B B' Q \]

Optimal pure codes of lengths 16 and 32 exist. We shall postpone the explicit constructions of pure optimal codes of the remaining lengths to Sec. V where the pasting of stabilizers is generalized to the pasting of noncommuting sets of generators. A typical example is the construction of an optimal pure code $[36] = [[36,29,3]]$ whose stabilizer is explicitly given in Table V. All the pure optimal codes of lengths $5 \leq n \leq 38$ with $n \neq 6$ are summarized in Table III.

Lemma 2 ensures that there exist $[17 - \beta]$ and $[38 - \beta]$ for $0 \leq \beta \leq 7$, i.e. optimal pure codes of those lengths exist and have 6 and 7 generators respectively. For $n > 38$ we have the following general construction:

**Theorem 3** Suppose $n > 38$ and $n \neq 8\epsilon m_f$ for any integer $m$ and $\epsilon = 0, 1$. a) If $8f_m - 1 \leq n \leq f_{m+2} - 4$ for some $m \geq 2$ then the stabilizer

\[ [8 \cdot (2^{2m-1} - \alpha)] [2^{2m}] [2^{2m-2}] [\ldots] [2^6] [17 - \beta] \]

defines an optimal pure code $[[n, n - 2m - 4, 3]]$ where $f_{m+2} - 4 = n = 8\alpha + \beta$ with $\alpha \geq 0$ and $0 \leq \beta \leq 7$. When $m = 2$ the stabilizer is generated by $[8 \cdot (8 - \alpha)] [17 - \beta]$. b) If $f_{m+2} - 3 \leq n \leq 8f_{m+1} - 2$ for some $m \geq 2$ then the stabilizer

\[ [8 \cdot (2^{2m-\alpha})] [2^{2m+1}] [2^{2m-1}] [\ldots] [2^7] [38 - \beta] \]
defines an optimal pure code $[[n, n - 2m - 5, 3]]$ where $8f_{m+1} - 2 - n = 8\alpha + \beta$ with $\alpha \geq 0$ and $0 \leq \beta \leq 7$. When $m = 2$ the stabilizer is generated by $[8 \cdot (16 - \alpha)] \triangleright [38 - \beta]$.

**Proof:** At first from Lemma 1 and the constructions of two codes families $[8 \cdot k]$ and $[2^k]$ it is clear that all the stabilizer codes involved in Eq. (12) or Eq. (13) are non-degenerate. Second by construction two families of codes $[8 \cdot k]$ and $[2^k]$ are stabilized by all $X$ and all $Z$ Pauli operators. As a result the stabilizer pasting can be applied from right to left so that Eq. (12) and Eq. (13) define pure stabilizer codes of distance $3$.

Now we evaluate the parameters of the codes. It is easy to see from the definition of $\alpha$ and $\beta$ and the identity $f_{m+2} = 2^{2m+2} + 2^{2m} + \ldots + 2^4 + 5$ that the length of the resulting codes are exactly $n$. Recalling that the codes $[8 \cdot k]$ and $[2^k]$ have $l_k = \lceil \log k \rceil + 5$ and $k + 2$ stabilizers respectively while the codes $[17 - \beta]$ and $[38 - \beta]$ have at most $6$ and $7$ stabilizers respectively. Since $\alpha \geq 0$ we have $\lceil \log(2^{2m-a} - \alpha) \rceil \leq 2m-a$ for $a = 0, 1$, the stabilizers in Eq. (12) and Eq. (13) have $2m+4$ and $2m+5$ generators, respectively.

As a first example when $n = 81$ we have $[81] = [2^6] \triangleright [17]$ which is an optimal code $[[81, 73, 3]]$ apparently missing from the public code table. As another example when $n = 305$ we have $m = 3$ and $8f_3 - 1 = 167 < 305 < f_3 - 4 = 337$ so that construction a) applies. Also we have $\alpha = 4$ and $\beta = 0$ and as a consequence $[305] = [8 \cdot 28] \triangleright [2^4] \triangleright [17]$. As a last example $n = 371$ we have $m = 3$ and $340 < n \leq 677$ with the condition of case b satisfied. In this case $677 - 371 = 8 \times 38 + 2$ so that $\alpha = 38$ and $\beta = 2$ and by construction Eq (13) we have $[371] = [8 \cdot 26] \triangleright [2^7] \triangleright [35]$. Both codes $[[305, 195, 3]]$ and $[[371, 360, 3]]$ saturate the quantum Hamming bound.

**IV. Exact bound**

In this section we shall prove the ‘only if’ part of Theorem 1, which amounts to showing that in the case of $\epsilon_n = 1$, i.e., $n = 8f_m + \{\pm 1, 2\}$ or $n = f_{m+2} - \{1, 2, 3\}$ for some $m \geq 1$, the quantum Hamming bound cannot be attained. Suppose that there is a pure code $[[n, k, 3]]$ that attains the quantum Hamming bound, i.e., a code whose stabilizer has $s_H$ generators. Let $[G_x, G_z]$ be its check matrix which is an $s_H \times 2n$ matrix satisfying $G_xG^T_x + G_zG^T_z = 0$. Because the code is supposed to be pure, the matrix $S = [G_x, G_z]G_z + G_x$, composed of the syndromes of all possible 1-qubit errors, must have distinct columns. Moreover we have $SS^T = 0$, meaning that $S$ is self orthogonal. Denote by $Y$ the $s_H \times y$ matrix composed of $y = 2^{s_H} - 3n - 1 < s_H$ column vectors that are not syndromes of any 1-qubit errors. Being composed of all possible $s_H$-dim vectors the matrix $HS$ is $[0, S][Y]$ self orthogonal and thus $Y$ is also self orthogonal. In other words, the matrix $Y$ is the check matrix of some classical binary self-orthogonal code $[y, k, 3]$ for some $k \leq s_H$. On the one hand it is an elementary fact that such self-orthogonal codes exist only for $y = 7, 8$ when $y \leq 10$ [4]. On the other hand in the case of $\epsilon_n = 1$ we have $y \in \{1, 4, 10\}$ if $n = 8f_m + \{\pm 1, 2\}$ while $y \in \{3, 6, 9\}$ if $n = f_{m+2} - \{1, 2, 3\}$. This contradiction proves that the qHB cannot be attained by a pure code in the case $\epsilon_n = 1$.

Now suppose that the code $[[n, k, 3]]$ attaining the qHB is impure. In this case some generators of the stabilizer act nontrivially only on 1) one qubit or 2) two qubits. In case 1) by removing this generator together with the qubit it acts on we obtain a code $[[n - 1, k, 3]]$ which may be pure or impure. From the qHB for the code $[[n - 1, k, 3]]$, i.e., $n - k - 1 \geq s_H(n - 1)$, and $s_H(n) = s_H(n - 1)$ in the case of $\epsilon_n = 1$, the bound Eq. (2) follows immediately. Therefore we can assume that case 1) does not happen.

In case 2) there are some single-qubit errors acting on different qubits that lead to an identical syndrome. We suppose that there is a number $v \geq 1$ of such degenerated syndromes with each syndrome caused by $u_i + 1$ single-qubit errors (acting on different qubits since case 1 does not happen) where $u_i \geq 1$ and $i = 1, 2, \ldots, v$. Because the product of two single-qubit errors that lead to the same syndrome is a stabilizer of the code, there is a $U$ of generators of the stabilizer that act nontrivially exactly on two qubits and obviously $|U| = \sum_{i=1}^v u_i := u \leq n - k$. According to Ref. [3] (Theorem 3.2) it holds

$$n - (u + v) \leq \frac{2n - k - u - v - 1}{3}.$$ (14)

Here we provide an alternative proof of the above inequality which may apply also to nonadditive codes. Let $W_i$ be the set of qubits that $u_i + 1$ single-qubit errors, which lead to an identical syndrome, act on and obviously $|W_i| = u_i + 1$ since different errors must act on different qubits. Because two different degenerated syndromes cannot be caused by single-qubit errors acting on the same qubit, we have a disjoint union $W_i$ with $|W_i| = u_i + v$. Let $W$ denote the remaining $|W| = n - u - v$ qubits that all the generators in $U$ trivially act on. Without loss of generality, applying some local Clifford transformations and relabeling the qubits when necessary, we can assume that those $v$ degenerated syndromes are caused by single-qubit errors $X_i$ with $i = 1, 2, \ldots, v$. Define

$$\hat{P}_1 = \hat{P} + \sum_{i=1}^v X_i\hat{P}X_i + \sum_{E_a, a \in W} E_a\hat{P}E_a$$ (15)

where $\hat{P}$ is the projector of the coding subspace of $[[n, k, 3]]$ and the last summation is over all possible 1-qubit errors $3(|W|)$ of them) in qubits belonging to $\hat{W}$. Note that each term in the definition of $\hat{P}_1$ is a projector and all these projectors are orthogonal to each other. Let $Q$ be the projector of the subspace stabilized by the generators in $U$ and obviously $TrQ = 2^n - |W|$’. Being also stabilized by $U$, the subspace $\hat{P}_1$ is a subspace $\hat{Q}$. As a consequence $Tr\hat{P}_1 \leq TrQ$, i.e., $(1 + v + 3|W|)TrP \leq 2^n - v$, which becomes exactly the inequality $Eq. (14)$ considering $TrP = 2^k$. From inequality $Eq. (14)$ it follows that an impure code attaining the qHB must satisfy $3n + 1 \leq 2^{s_H - u} + 3u + 2v$ which will be shown in what follows to be impossible when $\epsilon_n = 1$. Suppose $s_H \geq 6$. It follows from $\epsilon_n = 1$ that $3n + 1 \geq 2^{s_H - 10} + 10$ and we shall prove $2^{s_H - (1 - 2^u)} > 10 + 3u + 2v$. Indeed if $u \leq 6$ we have always $2^{s_H - (1 - 2^u)} \geq 2^6 - 2^{6 - u} > 10 + 5u \geq 10 + 3u + 2v$. If $u \geq 6$ we have $2^{s_H - (1 - 2^u)} \geq 63 \times 2^{s_H - 6} > 10 + 5s_H \geq 10 + 2v + 3u$.
since \( v \leq u \leq s_H \). Suppose now \( s_H = 5 \) and from \( \epsilon_n = 1 \) it follows \( n = 7, 9, 10 \). In case \( n = 7 \) inequality Eq.\([13]\) becomes, \( 22 \leq 2^{5-u} + 3u + 2v \). This is impossible because for \( u = 1, 2, 3 \) we have \( 22 - 2^{5-u} > 5u \geq 3u + 2v \) and for \( u \geq 4 \) we have \( 22 - 2^{5-u} > 14 + u \geq 3u + 2v \) since \( u + v \leq 7 \). In the cases of \( n = 9, 10 \) the inequality Eq.\([13]\), which becomes \( 28, 31 \leq 2^{5-u} + 3u + 2v \), is impossible because \( 2^{5-u} + 5u \leq 26 \) for \( 1 \leq u \leq 5 \). If \( s_H = 4 \) and \( \epsilon_n = 1 \) we have \( n = 4 \) and the corresponding code must be pure. All these contradictions show that the qHB cannot be attained by impure code either when \( \epsilon_n = 1 \).

V. Special constructions

In this section we shall prove Lemma 1 by constructing explicitly all the remaining optimal non-degenerate codes of lengths \( n \leq 38 \) except for \( n = 6 \). Our main tool is a generalization of the pasting of stabilizer codes to a pasting of 2-error detecting blocks (2ed-block) as defined below.

**Definition 4** A 2-error detecting block \([n, s]_e\) is generated by a set of \( s \) multilocual Pauli operators acting on \( n \) qubits with \( e \) pairs being non-commuting that detects up to 2-qubit errors.

Each non-degenerate stabilizer code \([n, s]\) detects all 2-errors and so they define 2ed-blocks \([n, s]_0\) with all the generators commuting. By shortening a pure code we generally obtain 2ed-blocks with some noncommuting pairs of generators. Some examples of 2ed-blocks are presented in Table IV.

**2ed-blocks pasting:** Given two 2ed-blocks \([n_2, s_2]_{e_2}\) and \([n_1, s_1]_{e_1}\) that are generated by \((S_1 = X(n_2), S_2 = Z(n_2), ..., S_{s_2})\) and \((T_1, T_2, ..., T_{s_1})\) respectively, then \( s = \max\{s_1, s_2, 2\}\) generators as in Table II is a 2ed-block \([n_1 + n_2, s]_e\) with \( e_1 + e_2 \leq e \leq e_1 + e_2 \). For convenience we shall denote by \([n_1, s_1]_{e_1} \triangleright \ [n_2, s_2]_{e_2}\) the resulting 2ed-block.

The 2ed-block given in Table II detects up to 2-qubits errors because firstly all the errors happening on the \( n_1\)-block or \( n_2\)-block can be detected because \([n_1, s_1]_{e_1}\) and \([n_2, s_2]_{e_2}\) are two pure codes of distance 3 and secondly two qubits errors happening on different blocks can be detected by the first two generators \(X(n_2) \otimes I(n_1)\) and \(Z(n_2) \otimes I(n_1)\). If two noncommuting generators are arranged in the same row the resulting generators will become commuting. As a result \( e \) can be zero when \( e_1 = e_2 \) and all noncommuting pairs are carefully matched. In this case we obtain a pure 1-error correcting stabilizer code, since all 2-qubit errors can be detected.

From the above arguments we see that although the 1-qubit block denoted as \([1]_1\) = \(X, Z\), detects only single qubit errors, it can be regarded as a 2ed-block because there is no 2-qubit errors on a single qubit block. For example we have \([2, 4]_2 = [1]_1 \triangleright [1]_1\). As another example the perfect code \([5, 1, 3]\) in Eq.\([3]\) can be regarded as the pasting of two 2ed-blocks \([4, 4]_1 \triangleright [1]_1\).

A 2ed-block fails to define a code because there are some pairs of noncommuting generators. By pasting two or more 2ed-blocks these noncommuting generators may become commuting and we thus obtain a 1-error correcting stabilizer code. Our construction is therefore a kind of puncturing plus pasting. By puncturing some old stabilizer codes we obtain some 2ed-blocks that generally contain some pairs of noncommuting generators. By pasting with some other 2ed-blocks and carefully matching their noncommuting pairs we are able to produce some new stabilizer codes. To complete the constructions given in Table III we have only to construct explicitly all the relevant 2ed-blocks.

We consider the optimal code \([2^5]\) as in Table V whose stabilizer is defined by the check matrix \([RH_5|A_5|RH_5]\) with

\[
A_5 = \begin{pmatrix}
1 & 1 & 0 & 0 & 0 \\
1 & 1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 \\
0 & 1 & 1 & 0 & 0 \\
1 & 1 & 1 & 0 & 0
\end{pmatrix}, \quad R = \begin{pmatrix}
1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 1 \\
1 & 1 & 0 & 0 & 0
\end{pmatrix}.
\]

Obviously \( A_5 \) is reversible and fixed-point free and \( R \) is invertible. By removing four coordinates \([c_5, c_{10}, c_{19}, c_{28}]\) from this \([2^5]\) we obtain the 2ed-block \([28, 7]_2\) and by removing the first four coordinates \([c_0, c_1, c_2, c_3]\) we obtain A 2ed-block \([28, 7]_1\). By 2ed-blocks pasting with 2ed-blocks in Table IV we obtain the pure optimal codes of lengths 30, 31, 33 and 35 in addition to a previously unknown optimal code

\[
[36] = [28, 7]_2 \triangleright [7, 5]_1 \triangleright [1]_1
\]

whose stabilizer is explicitly given in Table V.

From three partitions of \([2^4]\) as shown in Table VI we can obtain a pure optimal code \([10]\) as well as the unique optimal code \([6, 0, 4]\) of distance 4 and four different 2ed-blocks. By pasting with the perfect 5-qubit code we obtain \([15] = [10] \triangleright [5]\). Also we obtain all the optimal pure codes of lengths from 11 to 14 as well as an optimal pure \([7] = [6, 6]_1 \triangleright [1]_1\). Finally the remaining 2ed-blocks appeared in Table III are given in Table VII.

VI. Discussions

We have described a general construction of all the optimal stabilizer codes of distance 3 for lengths \( n > 38 \) by pasting known codes and a special construction of the optimal pure stabilizer codes of length \( 5 \leq n \leq 38 \) case by case by employing a generalization of the stabilizer pasting to noncommuting sets of stabilizers, i.e., 2ed-blocks pasting. For three families of lengths we have worked out analytically the
linear programming bound, which is strictly stronger than the quantum Hamming bound and ensures the optimality of our codes for these lengths. For all lengths except \( n = 6 \) there are pure optimal codes.

Apparentely the construction given by Theorem 2 is not unique. Firstly there are different constructions for the optimal code \([2^m]\) [7]. Secondly there are other constructions such as

\[
[8 \cdot (2^{2m-1} - \alpha_1)] \supset [8 \cdot (2^{2m-3} - \alpha_2)] \supset \ldots \supset [8 \cdot (2^3 - \alpha_{m-1})] \supset [17 - \beta] \quad (18)
\]

or

\[
[8 \cdot (2^{2m - \alpha_1})] \supset [8 \cdot (2^{2m-2} - \alpha_2)] \supset \ldots \supset [8 \cdot (2^3 - \alpha_{m-1})] \supset [38 - \beta] \quad (19)
\]

where \( \alpha_1 + 3 \leq 2^{2(m-1)+1} \) or \( 2^{2(m-1)+1} \) respectively and \( \alpha = \sum_{i=1}^{m-1} \alpha_i \). For different choices of \( \{\alpha_i\} \) the resulting codes may be inequivalent. This raises the problem of the classification of the optimal codes. Finally our approach should turn out to be useful to investigate nonbinary codes (see Ref. [3]) as well.

**Remarks** At time of finishing the first version of this paper the optimal codes of lengths \( n = 36, 37, 38, 81 \), which have been constructed in Ref. [4] have been missing in Grassl’s code table.
