Accepted 15 January 2013

Abstract – *Puya raimondii*, the giant Peruvian and Bolivian terrestrial bromeliad, is an emblematic endemic Andean species well represented in Huascarán National Park in Peru. This park is the largest reserve of puna (high altitude plateau) vegetation. The objective of this study is to report on genetic variation in populations of *P. raimondii* from Huascarán and neighboring areas. AFLP profiles with four selective primer combinations were retrieved for 60 individuals from different zones. Genetic variability was estimated and a total of 172 bands were detected, of which 79.1% were polymorphic loci. The results showed genetic differentiation among populations, and gene flow. A cluster analysis showed that individuals of *P. raimondii* populations located in different mountain systems could be grouped together, suggesting long distance dispersal. Thus, conservation strategies for *P. raimondii* have to take into account exchange between populations located far apart in distance in order to preserve the genetic diversity of this showy species.

Key words: AFLP, populations, gene flow, bromeliads.

INTRODUCTION

Bromeliads represent an important group with high diversity in Neotropics, particularly in America (only one species growth in Africa) (Benzing 2000). *Puya* is a genus with special importance in the Andes, and *Puya raimondii* Harms, dubbed “Queen of the Puna” by Antonio Raimondi (1874), is the most prominent constituent of this habitat and an emblematic plant of the Andean flora. Plants of this giant terrestrial bromeliad grow solely in puna, a high altitude Andean ecosystem, in a few regions of Peru and Bolivia, at elevations of 4000–4500 m asl. It is the largest Bromeliaceae in the world, reaching heights up to 12 m (Hornung-Leoni and Sosa 2005). This species is monocarpic, producing a single gigantic inflorescence at the end of its life. Plants take from 40 to 100 years to flower (Benzing 2000, Hornung-Leoni and Sosa 2004). Only a few individuals within a given population will bloom in any year (Benzing 2000, Hornung-Leoni and Sosa 2004), but when they do, hundreds of thousands of seeds are produced (Raimondi 1874).

The species is listed as endangered by the IUCN since its low number of individuals in scattered populations it is considered as an endangered species with only a few populations worldwide (www.iucnredlist.org). Although *Puya raimondii* is considered endangered in Peru (Law No. 043-2006-AG), only the country’s best-known *Puya* communities in Huascarán are protected. One of the main threats to these communities are fires, which are set to create pastureland, or the thorny leaves are burnt to facilitate access to the starch in the trunks for cattle fodder (Lambe 2008). Huascarán is the main national park in Peru, and Chanchayllo is not in a protected area. The first area is designated a Natural Heritage of Humanity and forms part of the UNESCO Biosphere reserves (<http://whc.unesco.org/en/list/333>). Ecotourism in Huascarán, where a significant number of populations of this species are located, is mainly based on *Puya raimondii*. This plant is notorious by the giant size compared with local flora (personal obs.). The species is considered one of the most important in Peru: an emblematic plant of the Andean flora.

There are previous genetic studies made in different genera of the family Bromeliaceae with allozymes, microsatellites, RFLP and AFLP markers (E.g. Murawski and Hamrick 1990, Rex et al. 2007). For *Puya*, the present study was only preceded by two interesting works with different biological units and hypotheses to investigate (Sgorbati et al. 2004, Schulte et al. 2010). Previous studies in *P. raimondii* determined the genetic structure of eight *Puya raimondii* populations in Huascarán-Peru and detected only 14 genotypes (Sgorbati et al. 2004). Only a few of the 217 AFLP marker loci screened were polymorphic and four populations were completely monomorphic, suggesting inbreeding.

The objective of this study is to determine genetic variation in populations of *Puya raimondii* in Huascarán National Park and neighboring areas (Canchayllo) in Peru using AFLP profiles. Individuals from two different mountains system were analyzed, in order to compare the genetic structure of populations in both areas, exploring AFLP markers with new primers. Both areas included in this study represent separated mountain systems ("Cordillera Blanca and Cordillera Negra"). In general, for plant populations, lack of genetic variation influences adaptation to habitats, rendering them even more vulnerable to anthropic pressure and climate change. It was hypothesized that, due to previous studies in Huascarán (Sgorbati et al. 2004), the genetic variation inside the national park will be low, and the values could be higher in neighboring areas.

MATERIAL AND METHODS

Study area

In this study, samples of both Huascarán and Canchayllo localities were included, which represent different mountain

systems separated by a valley (putative barrier). Mountains from Huascarán Park conform part of the "Cordillera Blanca" in the central province of Ancash and (9° 52' 37"- 9° 53' 27" S, 77° 15' 26"- 77° 16' 48" W; alt 4035-4600 m asl) and mountains from Canchayllo are in the "Cordillera Negra" (11° 49' 48"- 56.11" S and 75° 41' 44"- 42' 55.25" W; alt 3600-4100 m asl) (Table 1). Mountains from Huascarán have higher elevations than Canchayllo. Although both localities are in different mountain systems they represent the puna from Peru, which is a dry habitat with a variable climate in a single day (high fluctuations of temperature occur in a day, reaching 25 °C and in nights of intense cold, temperatures can drop below 0 °C), at high elevations (alt 3600-4200 m asl) in South American Andes with predominantly herbaceous plants (Ribera 1992). The localities in Peru where *P. raimondii* were collected are shown in Figure 1.

Genetic sampling

Leaf tissue was collected at field and preserved in silica gel. Five populations with a total of 60 individuals of *Puya raimondii* were sampled in Huascarán Park and in Canchayllo, and including 7 to 14 individual per population (Table 1), considering the collect permission suggestions.

DNA extraction and analysis

Total genomic DNA was isolated from silica gel dried leaf tissue. Samples were then frozen in liquid nitrogen with mercaptoethanol and ground to a power. For the extraction, it was used a modified 2x CTAB method (Doyle and Doyle 1989). DNA was treated with RNase and incubated for 30 min to eliminate RNA in the samples. DNA concentration was adjusted to 200 ng per µL for each sample.

Table 1. Genetic diversity in populations of *P. raimondii*

| Population/Individual | Locality | P | P (%) | Ht |
|-----------------------|--|-----|-----------------|---------------|
| R1/7 | N.P. Huascarán (9° 52' 37.1" S, 77° 16' 23.2" W) | 96 | 55.81 | 0.178 |
| R2/14 | N.P. Huascarán (9° 53' 00" S, 77° 15' 26" W) | 68 | 39.53 | 0.130 |
| R3/14 | N.P. Huascarán (9° 53' 26" S, 77° 16' 48" W) | 130 | 75.58 | 0.266 |
| R4/13 | Canchayllo (11° 49' 56.11" S, 75° 42' 55.25" W) | 87 | 50.58 | 0.172 |
| R5/10 | Canchayllo (11° 49' 48" S, 75° 41' 44" W) | 66 | 38.37 | 0.129 |
| Total (5/60) | | 136 | 79.07 | 0.230 ± 0.071 |
| | | | A | 1.791 ± 0.408 |
| | | | H _s | 0.197 ± 0.031 |
| | | | G _{st} | 0.144 |
| | | | Nm | 2.97 |

Note: Samples from Peru in the Canchayllo locality ("Cordillera Negra") were collected from 3600 to 4100 m (11° 49' 48"- 56.11" S and 75° 41' 44"- 42' 55.25" W); the samples from Huascarán Park, in the "Cordillera Blanca", were collected at 4035-4600 m (09° 52' 37"- 9° 53' 27" S, 77° 15' 26"- 77° 16' 48" W). In column Pop/Indiv. the number of populations is shown (R1 until R5), and the number of individuals are showed after diagonal line. P= number of polymorphic loci between species and populations. P% = percentage of polymorphisms. H_s= Nei's gene diversity for subdivided populations within species. A = mean number of alleles per locus, H_s = genetic diversity within populations. G_{st} = Coefficient of gene differentiation. Nm = gene flow. Values presented correspond to an average of all individuals of the species, and are reported with standard deviation (±). The analysis was performed for 60 individuals of *P. raimondii*. Total A, H_s, and H_s values are reported with standard deviation (±).

Figure 1. Map of studied populations. Collections were made from five *Puya raimondii* populations. R1–R3 are from Huascarán, and R4–R5 from Canchayllo, all from Peru. Both localities are separated by 300 km.

AFLP Analysis

The AFLP protocol reported by Vos et al. (1995) was followed using fluorescently labeled primers. Fragments were separated and observed using a LI-COR automated sequencer (model 4200, LI-COR, Lincoln, Nebraska). For the analysis, four selective AFLP primer combinations were used: EcoRI + AAG/MseI + ACC; EcoRI + ACG/MseI + ACC; EcoRI + AAC/MseI + ACC; EcoRI + AGG/MseI + ACC. Preliminary analysis was performed in laboratory to determine the primers that present variation in few samples. The primers which were selected due to these combinations show clearly a defined band for all samples, and showed variation in this preliminary tests.

Data analyses

Only unambiguously scorable polymorphic AFLP bands were recorded. For each individual, presence (1)

or absence (0) of each band was determined. Distance matrices were calculated using the Dice Index (Nei and Li 1979), and cluster analysis (UPGMA) was carried out using the Freetree program (Hampl et al. 2001). The bootstrap method proposed by Felsenstein (1985) was used to estimate confidence intervals for a group formed at each node by analyzing 1000 bootstrap replicates from the AFLP band data, using the Freetree program (Hampl et al. 2001). Only values over 50 percent were reported. An additional cluster analysis was carried out using the NTSYSpc 2.1 (Rohlf 1998), and the same dendrogram was obtained (data not shown). Also, a principal coordinate analysis (PCoA) was performed using the DICE similarity coefficient and DCENTER, EIGEN and PROJ procedures, with the software NTSYSpc 2.1 (Rohlf 1998).

Genetic diversity among (H_s) and within populations (H_d) was estimated; the coefficient of gene differentiation (G_{st}), number of alleles per locus, and gene flow (Nm) were also calculated to summarize data variation observed with dominant markers, such as AFLP. The observed allelic frequency for each population was used to estimate the mean number of alleles per locus (A) and the average proportion of polymorphic loci (P), based on Hardy-Weinberg expectations (Hartl and Clark 1997). All these calculations were conducted with the program Popgene, version 1.32 (Yeh et al. 1997). AMOVA analysis was conducted with Arlequin (Excoffier et al. 2005) for testing population structure and genetic variability among and within populations. The significance test was conducted using 10000 permutations. For population comparisons, 1000 permutations using F_{st} values were performed; in population differentiation, 10000 Markov steps, with 0.05 significance levels were carried out.

RESULTS AND DISCUSSION

AFLP polymorphism

The four primer combinations used in *P. raimondii* generated a total of 172 bands, of which 136 loci, representing 79.1% of the total, were polymorphic. Populations 1 (R1) and 3 (R3) from Huascarán showed the highest level of polymorphism, with 96 and 130 polymorphic loci, respectively (Table 1). Contrary with the hypothesis based on previous studies, individuals from *P. raimondii* from Huascarán showed higher level of polymorphism than individuals from Canchayllo (Table 1).

Genetic diversity

Individuals of *P. raimondii* from both Huascarán and Canchayllo populations showed a higher level of genetic variation (Table 1). In Table 2 it is shown that the genetic identity (values above in the diagonal) varies from high values, as 0.935 (R2-R1) and 0.977 (R3-R1), to values below 90% of identity (R5-R1= 0.732). If the genetic distance is analyzed (below diagonal), the value is lower in pop R1-R3 (0.024), and individuals from pop R1-R5 which are more distant genetically (0.312), values are greater.

The UPGMA dendrogram based on genetic distances from AFLP (Figure 2) showed two principal branches, with populations mostly grouped according to their geographic distribution. The majority of the individuals in subcluster I correspond to Huascarán, and those in II correspond to Canchayllo. However, populations of *P. raimondii* from Huascarán are mixed (R1, R2, R3) (Figure 2), and so are the populations of this species from Canchayllo (R4, R5). A few individuals from Huascarán appear to be mixed with populations from Canchayllo (e.g. one individual from population R2 with individuals from population R5). Population R5 of *P. raimondii* collected in Canchayllo showed a high genetic similarity. The PcoA graph shows individuals from different populations mixed (Figure 3). The first principal coordinate described 34.0 % of the total variation. The second principal coordinate described 16.5 % of the total variation. The two coordinates cumulatively account for 50.5%.

Clusters containing the majority of individuals of *P. raimondii* from the same geographical location were observed in the UPGMA diagram, suggesting genetic exchange from close populations (e.g. among R4 and R5 from Canchayllo and R1 to R3 from Huascarán). However, individuals from Canchayllo and Huascarán are also found in the same clusters, indicating significant gene flow between the two mountain systems. These results were similar to the PcoA graph, in which individuals from both localities are mixed. Canchayllo and Huascarán are almost 300 km apart. As a probable cause for the genetic exchange, it is suggested that the winged seeds of this bromeliad are able to disperse over long distances. In plants, a number of models of long-distance seed dispersal have been proposed, and long-distance dispersal is of critical importance to colonization of distant areas (Cain et al. 2000). This has also been noted for the bromeliad *Fosterella*, for which accidental long-distance dispersal has been suggested in order to colonize distant remote localities in Central America (Rex et al. 2007). Individuals from population R5 showed the minor genetic distance, and it was one of the populations with the fewest individuals in which only a single plant was flowering. Small populations are more susceptible to genetic drift and allele fixation, but gene

Table 2. Nei's genetic distances for *Puya raimondii*. Values below diagonal refers to genetic distance, and those above, to genetic identity

| Pop. ID | 1 (R1) | 2 (R2) | 3 (R3) | 4 (R4) | 5 (R5) |
|---------|--------|--------|--------|--------|--------|
| 1 (R1) | -- | 0.935 | 0.977 | 0.799 | 0.732 |
| 2 (R2) | 0.067 | -- | 0.945 | 0.877 | 0.835 |
| 3 (R3) | 0.024 | 0.056 | -- | 0.787 | 0.734 |
| 4 (R4) | 0.225 | 0.131 | 0.239 | -- | 0.852 |
| 5 (R5) | 0.312 | 0.180 | 0.309 | 0.160 | -- |

Figure 2. UPGMA dendrogram of AFLP markers based on genetic similarity. Individuals of *Puya raimondii* are represented by “r” and are followed by individual/population number. Bootstrap values greater than 50% are indicated. Note that individuals from both mountain systems appear mixed, but the cluster I is mainly composed by individuals from Huascarán, while in cluster II, the majority is composed by Chanchayllo samples.

flow, especially in long-lived species, can prevent genetic differentiation (Loveless and Hamrick 1984).

It has been indicated that monocarpy may reduce flowering population density, limiting mating possibilities (e.g. Tremetsberger et al. 2003). Moreover, the reproductive system determines the way genes are transmitted between generations; levels of genetic variability are consequently closely related to this. *P. raimondii* showed genetic variation at different levels even though it is a monocarpic species which takes a long

time to bloom. F_{ST} values showed moderate elevated values (0.32) of differentiation in allelic frequency. This finding was confirmed by the AMOVA analysis (Table 3), which showed significant differences between populations (32.1%), mainly within populations (67.9%). Genetic variation is caused by gene flow between populations as indicated by the values both of G_{st} and the results of the cluster analysis. The high heterogeneity (Ht) found within populations of this species (> 0.22) denotes a high genetic variation. High levels of

Dim-2 (16.54%)

Figure 3. Plot of the individuals of the first two axes of the PCoA. The first axis accounts for 34% of the variation, and the second axis, for 16.5%.

Table 3. Analysis of molecular variance (AMOVA) partitioning genetic divergence among nine populations of both species of Andean *Puya*. Significance tested by a permutation analysis against random partitioning of individuals (10000 permutations). Genetic differentiation among populations: $F_{ST} = 0.321$

| Source of variation | df | Sum of squares | Variance components | % of variation | p-value |
|---------------------|----|----------------|---------------------|----------------|---------|
| Among populations | 4 | 443.704 | 7.330 | 32.1 | < 0.001 |
| Within populations | 56 | 954.144 | 15.492 | 67.7 | < 0.001 |
| Total | 60 | 1387.847 | 22.822 | | |

genetic diversity have been found in other monocots such as *Yucca filamentosa*, a long-lived, semiwoody, predominantly outcrossing species with a wide geographical range (Massey and Hamrick 1998).

Sgorbati et al. (2004) discovered that populations of *P. raimondii* from Huascarán (Peru) had almost no genetic variation, and reported monomorphic populations showing 98.3% genetic similarity; they even suggested inbreeding depression. These results contrast with the 96.3% polymorphism found in the present analysis. Differences between their results and those of this study could be explained in a number of ways: 1) this study may have explored different localities; 2) it compared two different localities separated by barriers: Cordillera Blanca (Huascarán) and Cordillera

Negra (Canchayllo); and 3) it explored different combinations of primers. *P. raimondii* is distributed in Peru and Bolivia. Further investigation is needed to compare genetic diversity in the entire distribution area of this species.

The results of this study indicate that genetic variation is present in Peruvian populations of *P. raimondii*, the queen of the puna. Molecular markers used in this work revealed a high level of genetic variation; however, *P. raimondii* is subjected to extensive fire and exploitation in the Puna (Sgorbati et al. 2004, Hornung and Sosa 2005). Conservation of rare species must have maintenance of genetic diversity as a high priority (Pullin 2002). Continuous management and monitoring of populations is required to preserve them (Ouedraogo 1996); *in situ* conservation of *P. raimondii* in Huascarán National Park

could be an interesting program as a part of global conservation and management of natural biodiversity.

This study provides important information; namely, that in order to promote conservation areas for *P. raimondii*, genetic exchange of distant individuals must be taken into account. *P. raimondi*, together with the Andean Bear and the Andean Condor, are emblematic species that need to be conserved.

Variación genética na emblemática *Puya raimondii* (Bromeliaceae) no Parque Nacional Huascarán, no Peru

Resumo – *Puya raimondii*, uma bromélia terrestre gigante do Peru e da Bolívia, é uma espécie Andina endêmica e emblemática bem representada no Parque Nacional Huascarán, no Peru. O objetivo deste estudo é caracterizar a variação genética entre e dentro de populações de *P. raimondii* de Huascarán e áreas vizinhas. Perfis de AFLP com quatro combinações de oligonucleotídeos foram recuperados de 60 indivíduos provenientes de zonas diferentes. A variabilidade genética foi estimada, e um total de 172 bandas foram detectadas, das quais o 79,1% foram locos polimórficos. Os resultados mostraram a diferenciação genética entre as populações e o fluxo gênico. A análise de cluster mostrou que os indivíduos de populações de *P. raimondii* localizados em diferentes sistemas montanhosos agruparam-se, sugerindo dispersão a longa distância. Assim, estratégias de conservação para *P. raimondii* deve considerar o intercâmbio de indivíduos entre as populações localizadas a longa distância, a fim de preservar a diversidade genética desta espécie.

Palavras-chave: AFLP, populações, fluxo gênico, bromélia.
