ABSTRACT

This paper addresses the mixed analog-digital hardware implementation of a Hamming artificial neural network with on-chip learning. The developed integrated circuit architecture consists of a charge-based variable-weight neural network, and a digital module implementing the chip control, as well as the on-chip learning algorithm as a hardware-oriented adaptation of the well-known error-correction algorithm. Both the analog and the digital parts interact with each other to perform a pattern recognition task. A dedicated digital memory unit acts as the interface to temporarily hold the newly processed weights. We describe the actual realization as well as the design-flow which led to this development, including C software simulation, full-custom design and automated VHDL-based synthesis.

1. INTRODUCTION

Hardware realization of artificial neural networks aims at efficiently accelerating the processing speed of neural network specific tasks such as pattern classification, system control, and function predictions. Another aim is to increase the autonomy of systems to be integrated as specialized units into larger, neuro-computer based modular architectures, as well as into intelligent autonomous systems. This paper outlines the architecture and operation of a Hamming neural network classifier with on-chip learning ability.

The Hamming network [1] is a two-layer feed-forward network (see Fig. 1) with the ability to classify noise corrupted patterns, which has the property of always converging toward one of the patterns that was stored during a training phase, prior to the classification (recall) phase. The first layer known as the quantifier subnet computes the Hamming distance between the input pattern to be recognized (classified) and the patterns stored in the network as neuron's weight values. The second layer is the discriminator subnet which selects the first-layer neuron with highest amplitude response as the winner neuron : the one with the smallest Hamming distance to the current input pattern.

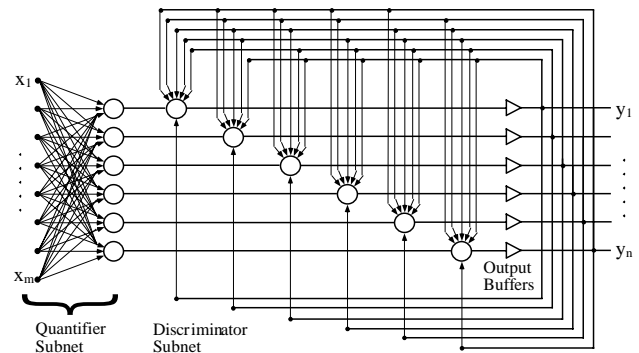

Figure 1: Schematic description of a Hamming network.

2. CIRCUIT ARCHITECTURE

The overall circuit architecture is a mixed analog-digital realization (see Fig. 2) [2] allowing a flexible and straightforward design-flow with reusability properties, while keeping the objective of efficient and compact design. It is well known that small silicon area and fast processing speed are the most relevant characteristics of analog VLSI circuits. Their drawbacks are in terms of sensitivity to noise and physical parameter mismatches, as well as difficulty in obtaining and storing large precision values. On the other hand, purely digital realizations exhibit better immunity to noise, allow easier and more flexible automation of the design process, and support a simpler interfacing with other digital units. One drawback of this approach is the limited, but well defined precision associated to the quantification of all processed values.

The Hamming network is realized as an analog module composed of a primary artificial neural network layer (ANN) of n charge-based neurons to perform the weighted sum of inputs, which drives a MOS-based WTA unit [3] of complexity $O(n)$ to carry out the classification task.

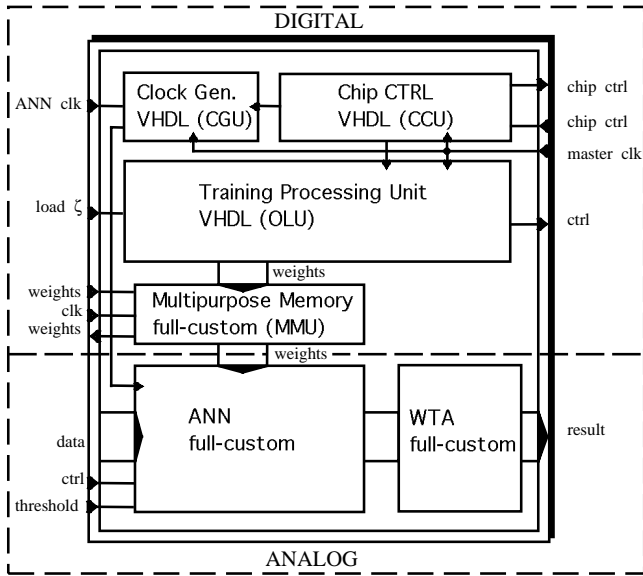

Figure 2: Block-diagram of the implemented architecture.

The Circuit Control Unit (CCU), Clock Generation Unit (CGU) and On-Chip Learning Unit (OLU) have been realized as purely digital units. Full-custom design methodology was applied to the design of all analog parts as well as to the design of the Multipurpose Memory Unit (MMU), which is the data interface between the analog and the digital parts, and also acts as a test structure. Significant emphasis was given to the development of macro-modules with a high degree of repeatability in order to easily regenerate the circuit by the means of parametrizable scripts. On the other hand, the digital parts were first designed and functionally validated in a high-level hardware description language (VHDL), to be synthesized and integrated as standard cells by a placement and routing software tool. Cell-based high-level synthesis offers a significant reduction of the design time and a technology independent development process for the relatively small cost (in our application at least) of reduced area efficiency.

3. HAMMING NETWORK INTEGRATION ISSUES

For the design of the Hamming network, we use a modified, adaptable weights version of the architecture first presented in [4]. Each of the n neurons in the primary layer (see Fig. 3) is composed of several charge-based synapses along a common dendrite. One synapse (see Fig. 4) is made of four binary weighted capacitors as well as four memory latches to support programmability of the weights. The bottom capacitor plates of one synapse (see Fig. 4 top) receive

the same input vector component (x_j), as the upper capacitor plates are tied together to build up the dendritic row. The capacitor values associated with each synapse are chosen as $C_{ij} = w_{ij} \cdot C_{unit}$, where C_{unit} (unit capacitance) = 17 fF in our realization. The capacitors are realized by comb-shaped POLY1-POLY2 overlaps resulting in exact integer multiples of the unit capacitance. Dummy capacitors are included in the architecture in order to equalize the total row capacitance, which is required for proper WTA operation. The 4-bit precision is not dictated by any limitation of the circuit technique; it was validated by careful simulations to perform satisfyingly in the pattern classification task. The noise immunity of the device is improved by a grounded MET1 shield on top of the capacitances.

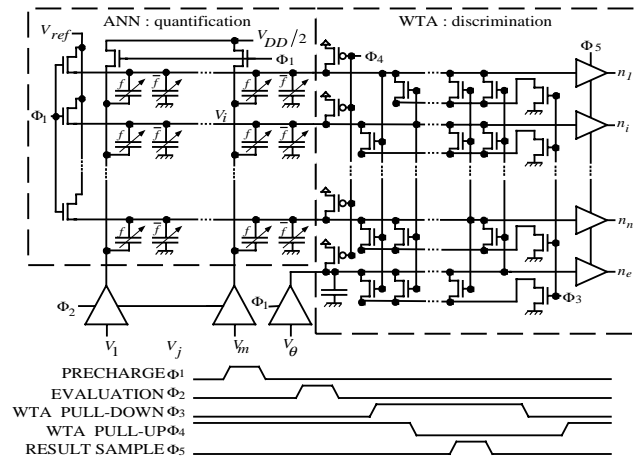

Figure 3: Gate-level description of the Hamming network.

The ANN operation requires five locally generated clock signals as illustrated in Figure 3. The quantification phase starts by precharging the synaptic lines to $V_{DD}/2$ and the rows to V_i on Φ_1 . The evaluation takes place on Φ_2 by applying a new pattern on the lines, which will perturbate each row voltage according to Equation 1, depending on the degree of matching between the new input data and the previously stored weights.

$$V_i = V_i + \sum_j x_j w_{ij} \frac{C_{ij}}{C_{total,i}} \quad (1)$$

Here V_i stands for the dendritic voltage after capacitive perturbation of row i ; V_j is the analog input voltage on line j ; $C_{total,i}$ is the total capacitance on one row, including par-

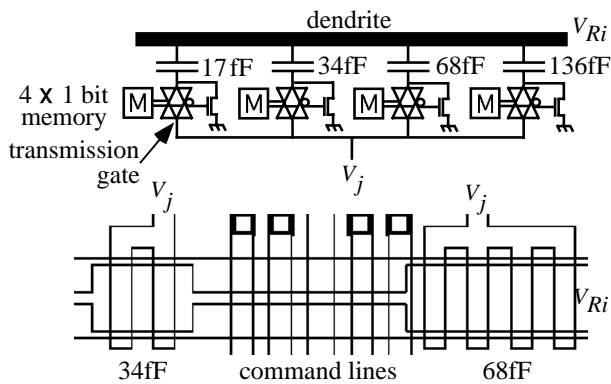

Figure 4: Top : circuit schematic of one synapse. Bottom : layout of two comb-shaped capacitors in the same synapse.

asitic capacitances; C_{ij} is the synaptic capacitance of between row i and line j .

The discrimination phase starts on the rising edge of V_{Ri} , that sets all dendritic voltages into competition; the winner selection is performed on V_{Ri} as the selection of the neuron with highest dendritic voltage. The classification result is sampled on V_{Ri} at the output.

The developed architecture operates in two distinctive modes, the *training mode* and the *forward processing mode* (recall) in which the ANN and WTA units assume different tasks. During the training phase each of the neurons (one at a time) has its weights updated each time its answer to the input vector is wrong. This answer is given by comparison of the dendritic voltage after perturbation against an external threshold level V_{th} by the WTA, which acts as a two-input voltage comparator to perform the non-linear hard-limiting activation function. While training one neuron into recognizing a specific pattern, all other neurons are being set in idle state in order to avoid unwanted perturbation of the process. In forward processing mode however, all the neurons are active and have their dendritic voltages perturbed by the input pattern. The WTA then acts as a multipoint sense amplifier that will raise the voltage of the winner and pull down to ground the dendritic voltages of all other neurons.

4. A HARDWARE-ORIENTED LEARNING ALGORITHM

The well known *error-correction learning rule* (see Equation 2) [5] was implemented in order to perform training of the ANN by updating its weights. A hardware-friendly adaptation of this algorithm, taking into account the requirement of a Hamming network for binary input vectors is inte-

grated in the OLU (see Equation 3). The V_{th} value is dictated to the system by the external supervisor controller to allow more flexibility than a hard-wired solution.

$$V_{Ri} = \sum_j V_j + V_{th} \quad (2)$$

Here V_j stands for the weight vector, V_{Ri} for the input vector, V_{th} is the expected output and V_{Ri} the actual neuron output result, η is the learning rate, Δt is the time increment.

$$V_j = \eta (V_{Ri} - V_{th}) \Delta t \quad (3)$$

where

$V_j = 1$ if $V_{Ri} > V_{th}$

or

$V_j = 0$ if $V_{Ri} \leq V_{th}$

A simulation software was developed in C language to validate the architecture as well as the algorithms on a pattern classification application. The model of neuron that was implemented takes all significant characteristics of the charge-based circuit technique into account. The architecture proved to work efficiently on classifying patterns belonging to the training set, as well as on generalizing on unseen vectors. Figure 5 illustrates a (10)-bit pattern recognition application. The patterns to be recognized were chosen so as to have a relatively low degree of correlation, since the number of input pixels is relatively small in this realization.

5. HARDWARE REALIZATION

An integrated hardware implementation of the described architecture was realized using the AMS (Austria Micro Systems) CMOS 0.8 micron technology (see Fig. 6). A network consisting of 20 neurons, each with 10 variable-weight synapses, was integrated. The die size is less than 1.5 mm^2 , while the active chip area (including ANN, learning-supervision unit, peripheral units and clock generator) is less than 0.5 mm^2 . Several test structures were also included on chip, to be packaged into a 100 PGA comprising several test pins. The small area of this realization confirms the area efficiency of our mixed analog-digital approach.

The test strategy included an extension of the VHDL model as well as the use of UNIX tools to automatically generate the test vectors into the appropriate format. An HP82000 ASIC tester was used for the low-end circuit test. All the constituting parts could be successfully validated. The test of the whole circuit requires the integration on a board including a soft-programmed microcontroller, thus building up a real-time interactive environment. Our modular architectural approach gives us high confidence for this further test, which has to be considered as part of the development of a specialized neuro-computer peripheral unit.

6. CONCLUSION

We have demonstrated in this paper the design methodology as well as the silicon integration of a charge-based Hamming artificial neural network. The neural network has a full-custom analog realization, while its learning-supervising unit has a VHDL-based digital realization, which ensures efficient area optimization and fast, automatizable design-flow. Further developments include board-level integration as a specialized neuro-computer peripheral unit, automatization of the design-flow into as a ANN silicon compiler, as well as the extension of the demonstrated principles to larger ANN architectures.
