Edited* by Peter T. Ellison, Harvard University, Cambridge, MA, and approved July 25, 2014 (received for review December 28, 2013)

The high energetic costs of human brain development have been hypothesized to explain distinctive human traits, including exceptionally slow and protracted preadult growth. Although widely assumed to constrain life-history evolution, the metabolic requirements of the growing human brain are unknown. We combined previously collected PET and MRI data to calculate the human brain's glucose use from birth to adulthood, which we compare with body growth rate. We evaluate the strength of brain-body metabolic trade-offs using the ratios of brain glucose uptake to the body's resting metabolic rate (RMR) and daily energy requirements (DER) expressed in glucose-gram equivalents (glucose_{RMR%} and glucose_{DER%}). We find that glucose_{RMR%} and glucose_{DER%} do not peak at birth (52.5% and 59.8% of RMR, or 35.4% and 38.7% of DER, for males and females, respectively), when relative brain size is largest, but rather in childhood (66.3% and 65.0% of RMR and 43.3% and 43.8% of DER). Body-weight growth (dw/dt) and both glucose_{RMR%} and glucose_{DER%} are strongly, inversely related: soon after birth, increases in brain glucose demand are accompanied by proportionate decreases in dw/dt . Ages of peak brain glucose demand and lowest dw/dt co-occur and subsequent developmental declines in brain metabolism are matched by proportionate increases in dw/dt until puberty. The finding that human brain glucose demands peak during childhood, and evidence that brain metabolism and body growth rate covary inversely across development, support the hypothesis that the high costs of human brain development require compensatory slowing of body growth rate.

A prolonged period of childhood and juvenile growth is a defining feature of human life history (1–3). Compared with other great apes, human offspring are weaned early, leading to an extended period of dependence on procured resources rather than breast milk (1, 4). Although this unique human reproductive pattern is viewed as shortening the interbirth interval and thus increasing fertility (5, 6), what is less clear is why humans also grow so slowly during childhood. Although most primates grow slower than other mammals (7), human childhood and juvenile growth stand out as unusually slow even by primate and great ape standards, during which it proceeds at a pace more typical of reptiles than of mammals (8, 9). In humans, a sizeable percentage of preadult growth is deferred until the pubertal growth spurt, when growth rate markedly increases and adult size is achieved (1).

Many hypotheses have been proposed to explain this slow and prolonged preadult life-stage, with most pointing to the extra time and energy required for human learning and brain development (5, 10–12). It has long been assumed that human cultural practices are sufficiently complex that they take many years to learn, which could have selected for a slowing down and extension of preadult development (13). A recent variant of this

idea notes the importance of complex extractive techniques to human foraging success, and proposes that humans have a long preadult stage to facilitate mastery of these skills (2).

Other hypotheses have focused on energetic trade-offs and viewed slowed growth as compensation for the brain's high energetic needs (1, 14–19). Because of its large size, the human brain has unusually high energy costs (15, 20, 21), which are particularly elevated compared with the body's metabolic budget early in the life cycle (18, 22). It has been estimated that the human brain accounts for between 44% and 87% of resting metabolic rate (RMR) during infancy, childhood, and adolescence (23–25), suggesting strong trade-offs with other functions. The human brain's demand for energy is sufficiently high during these periods that it could require that the body expend less on growth, thus slowing and prolonging the preadult period (1, 14–18, 26). This reasoning leads to the expectation that the ages of slowest body growth will coincide developmentally with peak brain metabolic needs.

Although the energetic trade-off concept is widely cited, the ability to test it against alternative hypotheses (2, 5, 10, 11) has been hampered by limitations of prior measures of brain metabolism during human growth. Direct estimates of total brain energy use have been based upon the nitrous oxide (N₂O) method, which quantifies brain oxygen consumption and estimates energy expenditure based on an assumption that glucose exclusively enters oxidative phosphorylation (24). However,

Significance

The metabolic costs of brain development are thought to explain the evolution of humans' exceptionally slow and protracted childhood growth; however, the costs of the human brain during development are unknown. We used existing PET and MRI data to calculate brain glucose use from birth to adulthood. We find that the brain's metabolic requirements peak in childhood, when it uses glucose at a rate equivalent to 66% of the body's resting metabolism and 43% of the body's daily energy requirement, and that brain glucose demand relates inversely to body growth from infancy to puberty. Our findings support the hypothesis that the unusually high costs of human brain development require a compensatory slowing of childhood body growth.

recent work shows that the rate of glucose uptake exceeds oxygen consumption in the brain (27), with up to 30% of brain glucose not entering oxidative phosphorylation during childhood (28). This additional use of glucose, in aerobic glycolysis, contributes to protein synthesis associated with synaptic growth and other important developmental functions (28–30), yet is not reflected in measures of oxygen consumption like N_2O , which therefore underestimate total brain glucose uptake and use.

Although past work points to high metabolic requirements of the growing human brain, data are available for only a small number of individuals of restricted age range, which limits their utility for evaluating trade-offs between brain metabolism and body growth during development. The only previous attempt to derive a growth curve for brain metabolism that we are aware of assumed that the mass-specific metabolic rate of the brain, measured using the N_2O method (24), is stable at adult-like levels across development (25, 31). Using this method, it was estimated that the brain accounts for 87% of RMR at birth, and that this fraction then steadily declines as the brain-to-body mass ratio decreases with age (25). This finding, if correct, would not support the hypothesis that ages of slowest body growth, in childhood, coincide with ages of peak brain metabolic requirements.

In contrast with the assumption that the per-gram brain metabolic rate is stable with age, PET studies show that glucose uptake in the cerebral cortex is more than twice as high during early- to midchildhood than in adulthood (32). This dynamism reflects the additional energetic costs associated with overproliferation of neuronal processes and synapses before activity-dependent pruning in late childhood and adolescence (33, 34), along with aerobic glycolysis, which is thought to rise in support of synaptic growth (27–29). In contrast, at birth, before extensive postnatal synaptic proliferation and the corresponding rise in aerobic glycolysis, PET-derived glucose uptake is 20–30% lower than in adults (32). Although past PET studies provide insights into the dynamics of glucose use at various stages of development, these studies only report point estimates in specific brain structures (32, 35), thus leaving the costs of the entire human brain during development—and potential evolutionary trade-offs with body growth—uncertain.

To quantify the metabolic costs of the human brain, in this study we used a unique, previously collected age series of PET measures of brain glucose uptake spanning birth to adulthood (32), along with existing MRI volumetric data (36), to calculate the brain's total glucose use from birth to adulthood, which we compare with body growth rate. We estimate total brain glucose uptake by age (inclusive of all oxidative and nonoxidative functions), which we compare with two measures of whole-body energy expenditure: RMR, reflecting maintenance functions only, and daily energy requirements (DER), reflecting the combination of maintenance, activity, and growth. We hypothesized that ages of peak substrate competition (i.e., competition for glucose) between brain and body would be aligned developmentally with the age of slowest childhood body growth, and more generally that growth rate and brain glucose use would covary inversely during development, as is predicted by the concept of a trade-off between brain metabolism and body growth in human life-history evolution.

Results

We first fit continuous functions to point estimates, inclusive of gray and white matter, of glucose uptake for the cerebrum, brainstem, and cerebellum in 29 individuals (32) ranging in age from birth to late adolescence (*SI Appendix, Fig. S1*). Regional glucose uptake rates were then multiplied by regional brain weights to obtain the daily grams of glucose consumed by the entire brain in both oxidative metabolism and aerobic glycolysis (for details, see *Materials and Methods*). Daily glucose use by the brain peaks at 5.2 y of age at 167.0 g/d and 146.1 g/d in males and females, respectively. These values represent 1.88- and 1.82-times the daily glucose use of the brain in adulthood (Fig. 1 *A* and *B* and *SI Appendix, Fig. S2*), despite the fact that body size is more than three-times as large in the adult.

Fig. 1. Glucose use of the human brain by age. (A) Grams per day in males. (B) Grams per day in females; dashed horizontal line is adult value (*A* and *B*). (C) $Glucose_{rmr}\%$ (solid line) and $Glucose_{der}\%$ (dashed line) in males. (D) $Glucose_{rmr}\%$ (solid line) and $Glucose_{der}\%$ (dashed line) in females.

To evaluate developmental changes in the strength of substrate competition between the brain and body, we next calculated the body's RMR and DER by entering the body weights (*SI Appendix, Fig. S3*) of the individuals for whom brain weights were obtained (37) into age- and sex-specific predictive equations (38). To allow direct comparison with brain glucose uptake, RMR (*SI Appendix, Fig. S4*) and DER (*SI Appendix, Fig. S5*) were first converted to grams of glucose equivalents (1 g glucose = 3.72 kcal of energy expenditure) (39). We expressed metabolic competition between brain and body as $Glucose_{rmr}\%$ and $Glucose_{der}\%$, calculated as the ratios between brain glucose uptake and daily glucose-gram equivalent RMR or DER, respectively. These ratios do not indicate the percent of RMR or DER used by the brain because some brain glucose uptake (the numerator) is not used in energy production (28). Instead, $Glucose_{rmr}\%$ and $Glucose_{der}\%$ can be interpreted as the fraction of the body's RMR or DER that could be met by the quantity of glucose consumed by the brain (see *SI Appendix, SI Materials and Methods* for details). In males and females, respectively, total brain glucose uptake is the equivalent of 52.5% and 59.8% of RMR at birth, drops to 37.5 and 40.8% of RMR in the first half-year, then rises to a lifetime peak of 66.3% and 65.0% of RMR by 4.2–4.4 y (Fig. 1 *C* and *D* and *SI Appendix, Fig. S6*). Although the brain accounted for a smaller fraction of DER, the pattern of glucose consumption relative to DER was very similar to that for RMR (Fig. 1 *C* and *D*): $Glucose_{der}\%$ accounted for the equivalent of 35.4% and 38.7% of DER at birth, declined to 24.7% and 26.8% by 7 mo, before rising to peak levels of 43.3% at 3.8 y (males) and 43.8% at 4 y (females). Adult $Glucose_{rmr}\%$ was 19.1% and 24.0% whereas $Glucose_{der}\%$ was 10.9% and 15.0% in males and females, respectively.

Finally, we compared age changes in $Glucose_{rmr}\%$ and $Glucose_{der}\%$ with body-weight growth velocity, calculated as the derivative (dw/dt) of the function linking body weight with age. Plotting unitless SD scores of $Glucose_{rmr}\%$ and dw/dt against age reveals opposing age trends in the two measures starting at 6 mo of age (Fig. 2 *A* and *B*). When SD scores of dw/dt are plotted against those of $Glucose_{rmr}\%$ (Fig. 2 *C* and *D*), the first 6 mo are characterized by a fast but decelerating rate of body-weight growth and a parallel reduction in $Glucose_{rmr}\%$. Starting at 6 mo, each increase in $Glucose_{rmr}\%$ is matched by a proportionate decrease in dw/dt , with peak $Glucose_{rmr}\%$ and the trough of dw/dt co-occurring. After the childhood peak in brain glucose demands, each subsequent age-related decline in $Glucose_{rmr}\%$ is accompanied by a proportionate increase in dw/dt until onset of pubertal weight gain

preschool age children (3–5 y) are lower than in later childhood and adolescence (38, 39, 42). These findings suggest that, like the body's very low expenditure on somatic growth, activity-related (discretionary) expenditure during human development is also comparatively low at ages of peak brain metabolic demand.

Pontzer et al. (43) recently showed that humans and other primates have reduced TEEs for their body sizes, despite having basal metabolic rates (BMRs) consistent with those of other mammals. The authors conclude that a reduced rate of energy throughput helps explain some shared features of primate life histories, including slower growth compared with other mammals. Pontzer et al. speculate that high brain energy needs might account for the fact that primate BMRs are not similarly reduced, but they also note extensive life-history variation among primates that traces to differences in allocation priorities. Our findings complement these data and implicate the high energy and substrate requirements of the brain, especially during the ages of most rapid development and learning, as a likely cause of life-history differences between humans and other closely related primates, such as chimpanzees.

Because the costs of neocortical synaptic growth and metabolism comprise a major endpoint for glucose in the brain, examination of the generalizability of the brain energetics–body growth trade-off hypothesis can be informed by data on postnatal synaptogenesis in other primates, which are available for humans, chimpanzees, and macaques. In all three species neocortical synapse densities are doubled during growth, compared with densities at birth. In macaques the period of peak synaptic density occurs during infancy, whereas in humans and chimpanzees peak synaptic densities take place during the midjuvenile or (in humans) childhood period (44). Brain energetics are thus not likely to impose a strong constraint on later juvenile body growth in macaques, whereas in chimpanzees growth is predicted to be slowed in the juvenile period, but to a lesser degree than in humans because of their smaller brains and corresponding lower brain metabolic needs (22). Comparative growth data support this prediction (41), showing that, unlike humans, chimpanzees and other great apes do not display marked declines in weight velocities after infancy. Additionally, humans are not distinct in having a “growth spurt” but in delaying it until after a long period of slow childhood growth (41).

Our findings also lead to the prediction that a slowing of preadult growth and increase in brain metabolism coevolved in the course of human evolution. Estimates of body growth from fragmentary and limited fossil hominin remains can be complicated; nonetheless, current data on hominin dental emergence, enamel growth rate, and skeletal growth suggest that a more extended period between weaning and sexual maturity began to appear at least 1.5 million y ago in *Homo erectus* (45). Data on dental eruption point to coevolution between brain expansion and maturational delay (45, 46), with a fully modern pattern of delayed physical growth not emerging until the origin of anatomically modern humans (47, 48). Although these findings are generally consistent with the hypothesis that brain expansion has set the pace for changes in body-size growth in the hominin lineage, our results underscore the challenges of interpreting the strength of metabolic trade-offs related to human brain evolution from data on the cranial capacity of fossils alone (e.g., ref. 14). In the modern human sample evaluated here, an average gram of brain tissue at 4 y uses more than 2.5-times the glucose of a gram of brain at birth (see data in *SI Appendix, Tables S1 and S2*). Absolute brain glucose requirements peak at ~5 y, several years before final brain size is achieved, and adult brain glucose requirements are only half those at age 5 y. This uncoupling of the energetic requirements of the brain from brain size reflects developmental dynamics in substrate-intensive processes related to neural plasticity and learning, which are not preserved in fossil samples. In this context, it is notable that, despite having similar cranial capacities, dental eruption data suggest that Neanderthals grew more rapidly than modern humans (48).

Although it is not possible to precisely evaluate the coevolution between brain metabolic requirements and slowing of body growth

from the fossil record, the ontogeny of brain metabolism that we document provides clues into the ecological strategies that were likely required for the modern human pattern of brain development to evolve. It has been noted that the high and inflexible glucose requirements of the developing human brain make it susceptible to impairment from nutritional shortfall (18). Despite this finding, we find that peak brain glucose uptake occurs after the age of complete weaning from breast milk in most human societies (4), and when the energetic buffer of body fat stores are near their lifetime nadir (18). In light of this finding, it seems likely that the evolution of human encephalization required cultural or social strategies to buffer the energy intake of dependent offspring. Rudimentary hunting and gathering economies appeared with the emergence of the genus *Homo* and are believed to have been important in supporting early brain expansion (49–51). A shift to calorically dense and easily digested foods, and greater food sharing among social groups, would have increased the nutritional quality and stability of the diet (14, 15, 20). Although direct evidence for childcare strategies are not preserved in the fossil record, recent comparative analyses suggest that cooperative care in raising and provisioning young was likely important in achieving levels of encephalization seen in *Homo sapiens* (52, 53). A system in which extended social networks provisioned food for children, combined with shifts to calorically dense and easily digested foods procured through hunting (14, 15), would have allowed the costs of human brain development to be widely distributed and also buffered against shortfall. This shift in the social context of human child rearing, occurring together with a protracted postnatal development of cortical connectivity (54, 55), likely created new opportunities for imitative learning and cumulative, intergenerational development of cultural traditions to become central features of the human adaptive complex (56, 57).

Our results also highlight underappreciated implications of the high glucose requirements of the human brain for medicine and public health. Diabetes is a condition in which tissues (primarily muscle) fail to respond appropriately to insulin, thus reducing glucose uptake. Although an important precursor to type 2 diabetes, peripheral insulin resistance is also effective at shunting scarce glucose to high-demand tissues or organs, such as to the fetus during the mild diabetes of pregnancy (58), or to the brain during the insulin-resistance triggered by stress (59). Changes in insulin secretion are believed to help coordinate glucose delivery to the brain as brain size and energy requirements change during development (60, 61). The present finding that the brain's requirement for glucose peaks after weaning, at an age when body fat stores are minimal (18), points to strong selection on physiologic mechanisms to redirect glucose delivery to the brain during nutritional stress. Studies report interactions between fetal undernutrition or small birth size and childhood weight gain as predictors of diabetes risk, suggesting an important role for childhood energetics and substrate availability in diabetes development (62, 63). Although normative data on developmental changes in insulin sensitivity during child development are lacking (64), our findings lead to the prediction that facultative buffering of substrate supply to the brain (e.g., insulin resistance induced acutely by stress) will be prominent at 4–5 y of age (59).

Measuring brain metabolism in living children poses unique challenges that warrant discussion. For ethical reasons, there is no study that includes PET and MRI data in the same healthy individuals spanning birth to adulthood. Consequently, we used brain volumetrics and glucose uptake rates obtained from two different United States samples deemed developmentally normal before screening (MRI) or after clinical assessments for possible abnormalities turned up negative (PET) (see *Materials and Methods* for more details). An additional limitation is that our analyses are based on cross-sectional brain and body-weight data, which pool fast- and slow-maturing individuals; this pooling can attenuate the apparent magnitude of the pubertal growth spurt while also obscuring the variable timings of its onset (65). Analytic techniques that account for variation in maturational tempo,

such as centering of individual growth curves on maturational indices rather than chronological age (65), would require repeat PET imaging in healthy individuals, which, as noted, is not ethical. The age of the trough in body-weight growth rate estimated from the cross-sectional data used here is consistent with mixed-longitudinal reference data showing lowest rates of weight gain from 4 to 4.5 y (66), and the latest World Health Organization (WHO) report on human energy requirements similarly finds that caloric needs for body growth are lowest at 4–5 y (38). Importantly, the cross-sectional body weights that we use to calculate RMR and the brain masses used to calculate brain glucose uptake were obtained from the same individuals, suggesting that our approach provides a useful basis for evaluating the changing relationship between brain metabolism and body size across a large sample varying widely in age and developmental stage.

In sum, we find that the rate of glucose uptake by the human brain, in both absolute terms and relative to the body's metabolic expenditure, does not peak at birth, when the size of the brain relative to the body is largest, but in childhood, when synaptic densities and related metabolic processes are maximal. These new estimates show that the ages when substrate trade-offs between the brain and body are greatest in humans coincide developmentally with the ages of slowest childhood body-weight growth, and that age-related changes in relative brain glucose needs and body-weight gain are tightly, inversely related from early infancy until puberty. These findings thus provide rare empirical support for the hypothesis that humans evolved a protracted period of slow preadult growth to compensate for the unusually high metabolic costs of brain development underlying the extraordinary human capacity for cultural learning.

Materials and Methods

PET Procedure. As described elsewhere (32, 67), glucose uptake was measured by one of the authors (H.T.C.) using PET in 36 individuals, including 7 healthy young adult volunteers (ages 19–30 y; mean 24.4 y; five males, two females) and 29 children (age range: birth to 15.5 y). The ICMRGlc values in the 29 children were compared with those of the seven healthy young adult volunteers, whose detailed neurological and psychological examinations disclosed no abnormalities. Written informed consent for the PET procedures was obtained directly from adult participants, and for minors, from parents, with institutional review board oversight by the University of California at Los Angeles Human Subject Protection Committee. Additional details of the PET protocol and sample have been described previously (32) and are discussed in the *SI Appendix, SI Methods and Materials*.

Continuous functions were fit separately to glucose uptake from the cerebrum, brainstem, and cerebellum (*SI Appendix, Fig. S1*). We first evaluated the fit of quadratic and cubic polynomial models using the Akaike Information Criterion (AIC). This process yielded quadratic models as best fitting for cerebellum and brainstem glucose uptake. Glucose uptake in the cerebrum followed a more complex age trend, which we modeled using a cubic spline function. Using the *mkspline* statistic in Stata v.11, we varied the number of knots, which were placed at age quantiles, and used the AIC to evaluate overall goodness-of-fit (68), yielding a 3-knot curve. Predicted values were calculated at 0.2-y intervals to allow the PET data to be combined with volumetric data and to calculate derived variables.

Volumetric Brain MRI Data. Total and regional brain volumes for 402 healthy males and females 4.6–20 y of age were obtained from the database established by the National Institutes of Health MRI Study of Normal Brain Development (36), of which one of us (N.L.) is an affiliate. Cerebrum was defined as whole-brain volume excluding the latter two structures. Longitudinal mixed-effects growth curve models were fit to these data, using the AIC for model selection, to yield the estimated regional volumes used here, with volumes predicted at 0.2-y increments. Additional details of the brain volumetry in this sample are described elsewhere (36) and in the *SI Appendix, SI Materials and Methods*.

We augmented the longitudinal MRI series with data from published and unpublished MRI studies that included total brain volume and volumes of the cerebrum, cerebellum, and brainstem in normal healthy subjects aged birth to 4.6 y (*SI Appendix, Table S3*). Because the MRI estimates before and after 4.6 y of age were derived from different populations with different body and brain sizes, it was not possible to splice absolute brain-region volumes to form single birth–adulthood growth curves. We therefore converted brain

region volumetric data from the various studies to regional weights [specific gravities: cerebrum 1.0335; brainstem 1.0277; cerebellum 1.0375 (69)], allowing calculation of the percentage of totally brain weight (TBW) accounted for by cerebrum, cerebellum, and brainstem (*SI Appendix, Fig. S7*), which were then multiplied by brain weights from the Dekaban and Sadowsky (37) brain-weight series spanning birth to adulthood. This study reports brain weights from autopsy records limited to the subset in which the brain was weighed soon after death and there was no indication of brain pathology, growth disruption, or gross overweight ($n = 1,004$ from birth to 15 y). To our knowledge, this highly cited data series is the only one available that reports brain and body weights from the same individuals, and that spans birth to adulthood. Using these data, we first modeled TBW with Gompertz and polynomial functions (spliced at 3.6 and 2.6 y in males and females, respectively) (*SI Appendix, Fig. S8*), which were multiplied by percent TBW for each region, yielding age-specific estimates of cerebral, cerebellar, and brainstem weights normalized to the same study sample (*SI Appendix, Fig. S9*).

Calculation of Total Brain Glucose Use. Glucose use by the cerebrum, cerebellum, and brainstem were calculated on 0.2-y intervals from the regional PET functions ($\mu\text{mol}/\text{min}$ per 100 g), which were multiplied by cerebrum, cerebellum, and brainstem weights. Global brain glucose use was calculated as the sum of cerebral, cerebellar, and brainstem glucose use (*SI Appendix, Fig. S2*).

RMR and DER. RMR (reflecting maintenance only) and DER (inclusive of maintenance, activity, and growth) were estimated from the body weights of the individuals included in the Dekaban and Sadowsky series (37). Weight data were first fit with cubic spline functions (*SI Appendix, Fig. S3*) with predicted values generated at 0.2-y intervals. We then used the most recent age- and sex-specific equations from the 2004 WHO recommendations on human energy requirements (38) to obtain RMR (*SI Appendix, Fig. S4*) and DER (*SI Appendix, Fig. S5*). To allow direct comparison with brain glucose uptake (only some of which is destined for use as an energy substrate; see below), we converted RMR and DER to glucose equivalents by multiplying by the conversion $1 \text{ kcal} = 0.2688 \text{ g}$ of glucose (39).

Calculation of $\text{Glucose}_{\text{rmr}\%}$ and $\text{Glucose}_{\text{der}\%}$. We quantify the strength of brain-body substrate trade-offs using the ratios $\text{glucose}_{\text{rmr}\%}$ and $\text{glucose}_{\text{der}\%}$, calculated as the ratio of brain glucose uptake (grams per day) divided by the body's RMR or DER (converted to daily glucose equivalents, assuming 1 kcal RMR or DER requires 0.2688 g glucose) $\times 100$. These ratios may be interpreted as the percentage of the body's RMR or DER that could be met by brain glucose uptake if all brain glucose were converted to energy via oxidative phosphorylation (see *SI Appendix, SI Materials and Methods* for detailed discussion). Because RMR was estimated from WHO age- and sex-specific predictive equations, there were discontinuities at the ages corresponding to changes in the predictive equations (at 3 and 10 y of age) (*SI Appendix, Fig. S4*). As a final step, we fit cubic spline functions to the male and female $\text{glucose}_{\text{rmr}\%}$ data (both 11-kn models), yielding continuous functions that minimized these irregularities (*SI Appendix, Fig. S6*).

Evaluating Trade-offs Between Brain Substrate Use and Body-Weight Growth. The derivative of the cubic spline function relating weight to age (dw/dt) was calculated in STATA and used as an estimate of body-weight growth velocity in this cross-sectional sample, which was compared with age changes in $\text{glucose}_{\text{rmr}\%}$ and $\text{glucose}_{\text{der}\%}$. All variables were first converted to SDscores to allow unitless comparisons.

Calculating Adult Values. To allow comparison with values at younger ages, mean body weights and TBW from the 19–21 y age bin in Dekaban and Sadowsky (37) ($n = 17$ females and 64 males), PET data from seven adult healthy volunteers, and MRI volumetry data for 20 y old subjects from the MRI study (36) were used to derive young adult values of RMR, regional brain weights, and brain metabolic rates (38). Adult DER was estimated as adult RMR \times a young adult PAL of 1.75 for males and 1.60 for females (38).

ACKNOWLEDGMENTS. We thank William Johnson for providing statistical advice on cubic spline curve fitting; Kim Hill for providing critical feedback Yarrow Axford for providing manuscript comments; Paul Aljabar and the Centre for the Developing Brain (Kings College, London) for providing unpublished brain volume data for healthy newborns; and three anonymous reviewers for providing critical feedback that strengthened the manuscript.
