ABSTRACT

In multiple sclerosis (MS) research, burden of disease and treatments efficacy are mainly evaluated with lesion load and atrophy. The former being poorly correlated with patient’s handicap, it is of interest to evaluate accurately the latter. A lot of methods to measure the brain atrophy are available in the literature. The brain parenchymal fraction (BPF) is one of these methods. It needs a precise segmentation of the brain and of the Cerebro-Spinal Fluid. However, artefacts like partial volume effects (PVE) can impair this classification. According to some articles, the BPF may also be less precise in longitudinal studies. To address these points, this article proposes a new method to evaluate the BPF which is based on an Expectation-Minimization framework taking into consideration the PVE. Modifications of the workflow are also proposed to improve its reliability in longitudinal study. Experiments have been conducted on simulated pathological images that validate the different measures.

Index Terms—Biomedical Image Processing, Magnetic Resonance Imaging, Multiple Sclerosis, Atrophy

1. INTRODUCTION

According to the modified McDonald criteria [1], number of MRI lesion and their location evaluations are mandatory to diagnose Multiple Sclerosis (MS). Lesions load measurement is also used in follow-up studies and pharmaceutical research as surrogate markers. Except for clinically isolated syndromes, clinical studies have shown that T2 lesions load is poorly correlated with patient’s handicap [2]. In consequence, other approaches like global atrophy measurement are studied.

Different techniques to quantify brain atrophy in MS are available [3]. One currently used method is the evaluation of the brain parenchymal fraction (BPF) [4]. This method required a precise segmentation of the cerebro-spinal fluid (CSF) compartment or of the brain (gray matter (GM), white matter (WM) and lesions). However, some voxels can contain a mixture of two classes (e.g. CSF and GM) because of image resolution: this Partial Volume Effect (PVE) may impair greatly the classification and subsequently the atrophy measurement. For example, sulci introduce a lot of GM/CSF PVE and this is one of the main problems that should be taken into consideration for obtaining a reliable CSF volume evaluation.

The BPF evaluation presents also other difficulties like variation of the segmentation results caused by the inter- and intra-image inhomogeneities or the skull-stripping step. The BPF seems more appropriate in group studies (e.g. MS patients vs. healthy controls) than in longitudinal studies [3], where a method measuring the changes (as SIENA¹ [5], that uses the local shifts in brain edges to evaluate the percentage brain volume change between two instants) should be preferred.

To improve the robustness of the atrophy measurement result and to address the PVE in CSF volume evaluation, we propose here a novel method to evaluate the BPF. First the segmentation algorithm is presented and is validated with simulated data for which the ground truth is available. Then we propose a method to improve the robustness of the measurement in longitudinal study and we compare our method with SIENA method. The remainder of this article is organized as follows: in Section 2, we describe the method workflow; sections 3 validates the different steps of the method; perspectives are discussed in Section 4.

2. METHOD

The proposed atrophy measurement method is divided in different steps. The different MRI sequences are preprocessed. Then, a multi channel Expectation Maximization (EM) classification method is applied. From this classification, different segmentations are generated. The computation of these segmentations’ volumes allows to evaluate atrophy.

2.1. Image normalization

When diagnosing MS, three MRI sequences are classically acquired: T1, T2 and Proton Density (PD) weighted images. T2 and PD are intrinsically coregistered but this is not the case of T1. As T1 has a higher resolution than T2 and PD, we register T1 on T2 [6] to limit the partial volume effect caused by the resampling.

2.2. Skull-stripping

Classification step is sensitive to a preliminary step, called skull stripping, which aims at isolating the brain in the image. Indeed, if this step is too restrictive, voxels belonging to the brain may be discarded, or conversely if it is too permissive, part of the meninges may be retained and subsequently misclassified. Different automatic skull stripping methods are available in the literature. As detailed in [9], we use a combination of Dugas et al. method [10], BET [11] and 3dIntracranial [12] to strip the skull.

2.3. EM classification method

The EM framework is currently used to classify brain MRI voxels. To take into consideration the different artifacts which are present in MS patients’ brain MRIs, we decided to classify voxels into ten classes: WM, GM, CSF, six GM/CSF PVE classes (with different proportions), and an outlier class, that will contain vessels and some MS lesions [10]. The probability density function (PDF) of each class is modeled by Gaussians, μ and σ denoting respectively the mean and standard deviation. Our PVE model approximates the intensities of a voxel which contains a proportion α of tissue x by

\[ I_{PVE} = \alpha I_x + (1 - \alpha)I_y, \]

PVE classes’ PDF then follows a Gaussian PDF with a mean of \((\alpha \mu_x + (1 - \alpha)\mu_y)\) and a standard deviation of \(\sqrt{\alpha^2\sigma_x^2 + (1 - \alpha)^2\sigma_y^2}\).

Following an initialization thanks to an affine registration of the MNI probabilistic atlas [13], our EM framework is then composed of three steps which are iterated:

- the Expectation step which consists of labeling of all classes (including PVE classes),
- the Maximization step which consists of estimation of the CSF, GM, WM, Outliers Gaussians parameters by maximizing the likelihood of the whole image,
- the computation of PVE classes’ parameters.

After the convergence of the algorithm, the final segmentations are obtained by classifying each voxel to the most probable class. MS lesions are classified mainly in the GM or outlier classes.

2.4. Volume and BPF computation

To consider the PVE in the volume computation, we generate CSF and brain repartition maps. These maps are not probabilistic segmentations of a compartment but give the proportion of the considered class (or compartment) in each voxel. CSF and brain repartition maps \(RM_{(CSF)}\), \(RM_{(B)}\) are obtained by equations 1 and 2 where \(SEG_{(PVE_0)}\) represents the segmentation of the PVE class with the proportion \(\alpha\) of GM.

\[ RM_{(CSF)} = \sum_{i=1}^{6} \frac{7-i}{7} \times SEG_{PVE_i} + SEG_{CSF} \]  
\[ RM_{(B)} = \sum_{i=1}^{6} \frac{i}{7} \times SEG_{PVE_i} + SEG_{GM} + SEG_{WM} \]

CSF and brain volumes are then obtained by the addition of all the voxel values of the considered repartition map, multiplied by the voxel volume, and yield the BPF.

\[ BPF = 100 \times \frac{\text{Brain Volume}}{\text{Brain Volume} + \text{CSF Volume}} \]

2.5. Atrophy computation

The BPF allows to compare different groups of population (e.g. MS patients vs. healthy controls). If acquisitions at different timepoints are available, the atrophy is given by the difference of successive BPF. However some part of the workflow process has to be changed. All the images are co-registered on the T2 sequence of the first timepoint. The intensities of images of the same sequence are equalized. The skull-stripped mask of the first timepoint is used for the following ones. In the EM classification, the class parameters are computed from the images of all timepoints. Then the obtained parameters are used to give the corresponding segmentations at each timepoint. Since outliers are not considered in BPF, this may bias the atrophy measure: to handle this, we consider the union of all outliers detected in each timepoint as outliers for all the timepoints.

3. VALIDATION

It is not realistic to validate the segmentation of PVE classes, since their PDF have a significant overlap. In consequence, an expert has first realized a qualitative validation by visual inspection of the results on real MRI but no significant error has been identified. Secondly, we realize a quantitative evaluation of the obtained segmentations on simulated data.

3.1. Segmentation comparison criteria

The first step of a validation is to identify comparison criteria. The classification method gives GM and CSF repartition maps but not binary segmentations. To compare these maps, we use a generalized version of the Similarity Index (SI), of the sensitivity (SEN) and the specificity (SPE) [14]. These criteria are given in Table 1 for a segmentation (Seg) with a reference image (Ref).

\[ R_{\text{f}(i)} = \frac{\text{Seg}(i)}{\text{Ref}(i)} \]  
\[ S_{\text{Seg}(i)} \] represents the intensity of the voxel i in the corresponding image.

The generalized criteria give the same results with the conventional criteria on binary images. Moreover their values remain between 0 and 1.
3.2. Segmentation comparison results

The segmentation method has been validated using the BrainWeb\(^1\) simulated images. Sequences (Noise: 3\%, Intensity non-uniformity: 20\%, slice thickness: 1 mm) have been generated using the moderate MS lesions brain anatomical model. From this first ground truth, we also generate images with a slice thickness of 3 mm that are considered as ground truth repartition maps. We evaluate our method with images generated by BrainWeb with slice thicknesses of both 1 and 3 mm. The results of this evaluation are given in table 2.

Table 2. Segments comparison results for Brainweb MS anatomical model.

<table>
<thead>
<tr>
<th>Slide thickness</th>
<th>Tissues</th>
<th>SI</th>
<th>SEN</th>
<th>SPE</th>
</tr>
</thead>
<tbody>
<tr>
<td>MS 1mm</td>
<td>CSF</td>
<td>0.81</td>
<td>0.79</td>
<td>0.99</td>
</tr>
<tr>
<td>MS 1mm</td>
<td>Brain</td>
<td>0.98</td>
<td>0.98</td>
<td>0.99</td>
</tr>
<tr>
<td>MS 3mm</td>
<td>CSF</td>
<td>0.82</td>
<td>0.81</td>
<td>0.99</td>
</tr>
<tr>
<td>MS 3mm</td>
<td>Brain</td>
<td>0.95</td>
<td>0.98</td>
<td>0.97</td>
</tr>
</tbody>
</table>

The obtained results yield correct segmentations ($SI > 0.8$). The sensibility values are correct ($SEN > 0.79$) even if they seem to indicate a slight under segmentation. The specificity values ($SPE > 0.97$) indicate that there are few false positive voxels. The CSF results are slightly weaker than Brain (GM+WM) results. This can be explained by the fact that CSF compartment compared to GM or WM represents the smallest volume. This explains that any misclassified voxels will introduce a larger relative error to the CSF classification rather than to the Brain (GM+WM) classification.

3.3. Volume measurements validation

Table 3 gives the relative error in CSF and brain volume measurements. GM and WM volume estimation errors are quite important but the error on the brain volume is acceptable. Moreover we have a good estimation of the CSF volume. The average CSF volume error is equal to 4.5\% where the CSF volume is the smallest compared to the others.

3.4. Atrophy measurements validation

A simulation of normal aging atrophy which uses BrainWeb images has been proposed in [15]. We use this simulation to validate our global atrophy measurement which is obtained by the difference of the BPF between two timepoints. Figure 1 shows the measured atrophy versus the simulated atrophy, ours being a little higher (a perfect measure will yield a slope equal to one), our measures being closest to the simulated atrophy. Both methods exhibit a good correlation with the simulated atrophy, ours being a little higher ($R^2 = 0.99, p < 0.05$). It should also be noticed that the linear approximation resulting from our measures goes through the origin (the point (0, 0)), which is expected, while SIENA does not. This could suggest a slight superiority of our method without modification for longitudinal studies yield incorrect results. Our method with longitudinal study modifications underestimates atrophy while SIENA overestimates it (a perfect measure will yield a slope equal to one), our measures being closest to the simulated atrophy. Both methods exhibit a good correlation with the simulated atrophy, ours being a little higher ($R^2 = 0.99, p < 0.05$). It should also be noticed that the linear approximation resulting from our measures goes through the origin (the point (0, 0)), which is expected, while SIENA does not. This could suggest a slight superiority of our method with respect to SIENA, but this has to be confirmed with further experiments.

4. CONCLUSION AND FUTURE WORK

The proposed method allows to obtain repartition maps of the different brain compartments. From these repartition maps, which give the proportion of the different compartments in each voxel, the volume of CSF and of the brain (GM+WM) can be computed. These volume evaluations are robust to artefacts like PVE and MS lesions in the images thanks to the inclusion of PVE classes and of an outlier class in the classification process. From these, a BPF can be computed. In the case of longitudinal study, the difference of the two obtained BPF give an atrophy value which has been shown to be strongly correlated to the real brain atrophy (on simulated data). In this case, the BPF was not less precise than SIENA.

Because of the lack of simulated images with MS brain atrophy, the next step will consist comparison of the atrophy measurements of our method against other methods on real MS patient MR images. To that end, we are currently collecting MR images from a multi-center study. For the moment, we do not have enough patients with several acquisitions to present statistically significant results. Preliminary results on a few patients are promising. Obtained segmentations were qualitatively validated by experts and the obtained volumes and atrophy measurements are in accordance with the literature [3].

Acknowledgments

We are very thankful to Oscar Camara of the Centre for Medical Image Computing (UCL) for providing us with simulated atrophy images.
