**Abstract:** The broad application of electrospun nanofibrous scaffolds in tissue engineering is limited by their small pore size, which has a negative influence on cell migration. This disadvantage could be significantly improved through the combination of nano- and microfibrous structure. To accomplish this, different nano/microfibrous scaffolds were produced by hybrid electrospinning, combining solution electrospinning with melt electrospinning, while varying the content of the nanofiber. The morphology of the silk fibroin (SF)/poly( $\epsilon$ -caprolactone) (PCL) nano/microfibrous composite scaffolds was investigated with field-emission scanning electron microscopy, while the mechanical and pore properties were assessed by measurement of tensile strength and mercury porosimetry. To assay cell proliferation, cell viability, and infiltration ability, human mesenchymal stem cells were seeded on the SF/PCL nano/microfibrous composite scaffolds. From in vivo tests, it was found that the bone-regenerating ability of SF/PCL nano/microfibrous composite scaffolds was closely associated with the nanofiber content in the composite scaffolds. In conclusion, this approach of controlling the nanofiber content in SF/PCL nano/microfibrous composite scaffolds could be useful in the design of novel scaffolds for tissue engineering.

**Keywords:** silk fibroin (SF), poly( $\epsilon$ -caprolactone) (PCL), nanofibers, microfibers, composite scaffolds, bone regeneration

## Introduction

The aim of tissue engineering and regenerative medicine is to repair and regenerate damaged tissue using scaffolds, a substitute for body tissue. Scaffolds are used to mimic the structure and biological functions of the naturally occurring extracellular matrix (ECM). ECM, the ideal model of scaffolds, plays the role of structural framework in tissue, leading to cell adhesion and the secretion of ECM protein to assist in the regeneration of damaged tissue.

Scaffolds have several requirements for use in tissue regeneration.<sup>1</sup> First, they must have good biocompatibility to prevent inducing a foreign-body reaction after implantation. Second, it is necessary for the scaffolds to have a hydrophilic surface to facilitate cell attachment. Third, scaffolds must possess a highly open porous structure to provide mass transfer of oxygen and nutrients. In addition, good biodegradability and structural stability are needed to provide an optimal regeneration environment.<sup>1,2</sup> The mechanical properties and degradation rate of scaffolds are decided based on the regeneration period and the type of target tissue.

Nanofibrous scaffolds have been recognized to have potential in this field because of their structural similarity to natural ECM, consisting of nanofibers ranging in diameter

from 50 to 500 nm.<sup>3</sup> The three most important methods that can be used for the fabrication of nanofibers are phase separation, self-assembly, and electrospinning.<sup>4</sup> Phase separation can be used to obtain nanofibrous foams; however, it has many processing variables, such as the solvent, type of polymer, polymer concentration, and solvent exchange. Self-assembly has similar disadvantages, such as material limitations, and is a time-consuming process. Electrospinning is a widely used economical and simple technique for the fabrication of micro- to nanometer-size fibers from various polymers. Much of the current research has focused on the potential of electrospun fibrous scaffolds for tissue-engineering applications.<sup>5</sup> Kurpinski et al<sup>6</sup> improved cell adhesion through the heparin coating of an aligned nanofiber web, by controlling the rotating drum speed. Bini et al<sup>7</sup> investigated the regeneration of nerve cells using an artificial poly(L-lactide) nerve conduit which was fabricated by electrospinning on a rotating Teflon tube. Sahoo et al<sup>8</sup> studied woven silk scaffolds with poly(lactic-co-glycolic acid) nanofibers for connective tissue regeneration. However, electrospun nanofibrous scaffolds still have limitations for three-dimensional culturing due to their small diameter.<sup>9</sup> Furthermore, cells cannot migrate within its dense structure due to the relatively small pore size (less than 5  $\mu\text{m}$ ) compared to cellular diameter (5–20  $\mu\text{m}$ ).<sup>6,9–12</sup>

In order to overcome these problems, newly designed nano/microfibrous composite scaffolds were fabricated through a hybrid electrospinning system (Figure 1). The hybrid electrospinning system was designed by combining melt electrospinning with traditional solution electrospinning. Traditional electrospinning systems can produce fibers with diameters of up to ~10  $\mu\text{m}$  using highly concentrated polymer solutions.<sup>9</sup> However, fiber diameters of a few micrometers are not sufficient to manufacture scaffolds with a highly porous three-dimensional structure. Therefore, in this approach, the melt-electrospinning system was used to prepare microfibers with diameters above several dozen micrometers. In the 1980s, Larrondo and St John Manley<sup>13–15</sup> first reported the electrospinning of a molten polymer. Lyons et al<sup>16</sup> reported a relationship between molecular weight and fiber size in this system. Zhou et al<sup>17</sup> then obtained polylactic acid nanofibers by melt electrospinning in a guided heating chamber. Guided heating chambers control the air temperature of the space between the needle tip and collector. This process is eco-friendly, because it uses molten polymers as a spinning dope instead of polymer solutions dissolved in organic solvents.

This study investigated the hybrid electrospinning of silk fibroin (SF)/poly( $\epsilon$ -caprolactone) (PCL) nano/microfibrous composite scaffolds with various compositions. PCL is

**Figure 1** Schematic diagrams of the hybrid electrospinning system and an SF/PCL nano/microfibrous composite scaffold.  
**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin.

a US Food and Drug Administration-approved synthetic polymer, and is well known for its hydrolytic and enzymatic biodegradability.<sup>18</sup> It is a good bone-scaffolding material because it can take several years to degrade in vivo, and is biocompatible and relatively inexpensive.<sup>19</sup> Furthermore, its low melting temperature makes it suitable for melt electrospinning.<sup>20</sup> In this study, PCL was used as the main component in the microfibers. SF, a natural fibrous protein, gives high mechanical strength, elasticity, and softness.<sup>21,22</sup> It is widely used in the biomedical field, due to its excellent biocompatibility.<sup>23–26</sup> To improve the characteristics of the fibers through this study, PCL microfibers were selected for their ability to form micropores to support cell migration, while SF nanofibers were employed to mimic the structure of natural ECM for cell adhesion. The electrospun SF/PCL nano/microfibrous composite scaffolds were characterized in terms of surface morphology, porosity, mechanical properties, cell attachment, and bone regeneration.

## Materials and methods

The regenerated SF sponges were obtained from degummed silk yarn in the same manner as our previous study.<sup>27</sup> The solvent of the SF sponge, 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP), was purchased from Acros Organics (Belgium) and used as received. PCL ( $M_n = 75,000$ ) was purchased from Dow Chemical (Tone 767; USA).

## Preparation of SF/PCL nano/microfibrous composite scaffolds

To fabricate nano/microfibrous composite scaffolds, solution electrospinning and melt electrospinning were combined. Figure 1 shows a schematic of the hybrid electrospinning system and nano/microfibrous composite scaffold fabricated by hybrid electrospinning. In order to carry out melt electrospinning, PCL pellets were placed in a stainless steel syringe, and then heated to a temperature of approximately 150°C using a hot-oil circulator. The PCL melts were melt electrospun simultaneously with electrospinning of the SF solution. A stainless steel syringe with a 21 G needle was placed at a distance of

10 cm from the plate-type collector. Voltage was applied at 17 kV with a flow rate of 1 mL/h. The regenerated SF sponges were dissolved in HFIP at a concentration of 3 wt% (w/v) to prepare the SF solution for solution electrospinning. The SF solution was then electrospun on a target drum that was placed at a distance of 8 cm from the syringe tip (24 G). Several SF/PCL nano/microfibrous composite scaffolds were fabricated at different weight ratios of SF nanofiber, which were prepared by controlling the flow rate of SF solution during electrospinning (Table 1). Weight ratios were calculated from the relation between the spinning conditions of molten PCL and SF solution. The total deposition weight of melt-electrospun PCL microfibers can be acquired from the density and mass flow rate per hour of molten PCL. The weight of the electrospun SF nanofibers during deposition can be estimated from the concentration and mass flow rate per hour of the SF solution. The examined ratios of SF nanofiber to PCL microfiber were 0:100 (PCL 100), 2:98 (SF/PCL 2/98), 4:96 (SF/PCL 4/96), 6:94 (SF/PCL 6/94), and 8:92 (SF/PCL 8/92) (w/w). The SF/PCL nano/microfibrous composite scaffolds were treated with water vapor at 40°C for 4 hours to cross-link the regenerated SF nanofibers.<sup>28,29</sup> The water vapor-treated SF/PCL nano/microfibrous scaffolds were then washed with distilled water for 1 hour and dried in a vacuum for 24 hours at room temperature.

## Characterization of composite scaffolds

The surface morphology and pore structure of the SF/PCL nano/microfibrous composite scaffolds before and after water-vapor treatment were observed with a field-emission scanning electron microscope (SEM; JSM-7000F; JEOL, Japan). Prior to the observation, the specimens were coated with platinum through ion sputtering for a few seconds. The average diameter and diameter distributions were obtained by analyzing the SEM images with a customized image-analysis program (Scope Eye II; TDI, South Korea). The pore properties of the SF/PCL nano/microfibrous composite scaffolds were measured with a mercury porosimeter (AutoPore IV 9520; Micrometrics, USA). The tensile properties were measured ten times on a tensile tester (model 4467; Instron,

**Table 1** Electrospinning processing conditions for the PCL microfibrous scaffold and SF/PCL nano/microfibrous composite scaffolds

	SF concentration (wt%)	Voltage (kV)	Flow rate (mL/h)	TCD (cm)	Needle gauge (G)
PCL 100	–	17	1	10	21
SF/PCL 2/98	3	7	0.8	8	24
SF/PCL 4/96	3	8	1.6	8	24
SF/PCL 6/94	3	8.5	2.4	8	24
SF/PCL 8/92	3	9	3.3	8	24

**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin; TCD, needle tip-to-collector distance.

USA), according to the ASTM D638-10 standard test method. The dog-bone-shaped specimens were characterized with an elongation speed of 10 mm/min and a load cell of 50 N. Ten independent measurements for each sample were averaged, except maximum and minimum value.

## Plasma treatment

Before the cell-culture and animal tests, the PCL microfibrillar scaffold and SF/PCL nano/microfibrillar composite scaffolds were treated with  $\text{NH}_3$  plasma using a MiniPlasma station (Plasmart, South Korea) to increase their hydrophilicity.<sup>30,31</sup> The chamber was evacuated to less than 10 mTorr before it was filled with  $\text{NH}_3$  (100 mL/min), followed by the generation of glow-discharged plasma (20 W) for 50 seconds.

## Cell culture

To obtain human mesenchymal stem cells (hMSCs), bone marrow was aspirated from the alveolar bone of patients during oral surgery. All patient participation was approved by the Institute Research Review Board in the Department of Periodontology at Wonkwang University Dental Hospital. The properties of the hMSCs were discussed in our previous study.<sup>32</sup> The cells were cultured in  $\alpha$ -modified Eagle's medium (Gibco, USA) containing 10% fetal bovine serum and 1% antibiotics (penicillin G 10,000 units/mL, amphotericin B 25  $\mu\text{g}/\text{mL}$ ; Gibco) and incubated at 37°C in a 5%  $\text{CO}_2$  environment. In this study, cells passaged three to six times were used, and the culture medium was changed every 2 days. PCL 100, SF/PCL 2/98, and SF/PCL 6/94 scaffolds were cut into small rounds of 5 mm, 12 mm, and 30 mm in diameter, and these specimens were transferred to 96-well, 24-well, and six-well tissue-culture dishes, respectively. All specimens were sterilized with ethylene oxide gas. In this study, the 5 mm rounds were used for the 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS) assay, and the 12 mm rounds were used for Live/Dead and alizarin red sulfate (AR-S) staining.

## MTS assay

Proliferation of the cells attached to and subsequently grown on the scaffold was assessed using CellTiter96<sup>®</sup> Aqueous One solution (Promega, USA). Briefly, hMSCs were seeded on sterilized specimens 5 mm in diameter in a 96-well culture dish. For measurement at the indicated intervals, 25  $\mu\text{L}$  of MTS reagent was added to each well and incubated for 4 hours. Absorbance was measured at 490 nm on an enzyme-linked immunosorbent assay reader (SpectraMax M3; Molecular Devices, USA).

## Live/Dead staining

To assess cell viability, a Live/Dead<sup>®</sup> viability/cytotoxicity kit (Molecular Probes, UK) was used. Briefly, hMSCs were seeded on sterilized specimens 12 mm in diameter in a 24-well culture dish. After 5 days of culturing, the scaffolds were washed with phosphate-buffered saline for 30 minutes to remove the phenol red and serum, and then incubated in Live/Dead viability/cytotoxicity solution. Healthy cells stained with calcein acetoxymethyl (AM; 0.05%) were seen in green, while the ethidium homodimer-1 (EthD-1, 0.2%)-stained nuclei of the dead cells appeared in red. After staining, the sample was observed under a fluorescence microscope (DM IL LED Fluo; Leica, Germany).

## Cell infiltration

After 5 days of cultivation, the scaffolds cultured with cells were embedded in optimum cutting temperature compound (TissueTek, USA), cut into sections 10 mm in thickness, and fixed onto microscope slides. The sections were fixed in 10% formalin, and then stained with hematoxylin to visualize cell infiltration into the scaffold.

## Osteoblast induction

To induce osteoblast differentiation of the hMSCs, the cells were treated with osteogenic differentiation stimulant (OS): 10 mM  $\beta$ -glycerophosphate (Sigma, USA), 50  $\mu\text{g}/\text{mL}$  ascorbic acid (Sigma), and 0.1 mM dexamethasone (Sigma). The OS treatment was repeated every 2 days during osteoblast induction.

## AR-S staining

Calcium accumulation was determined using AR-S (Sigma) staining. The hMSCs were cultured on scaffolds in a 24-well culture dish for 19 days with continuous OS treatment. Extracellular mineralization was induced by adding 4 mM  $\text{NaHPO}_4$  (Sigma), then the medium was removed and cells were rinsed with PBS. Fixation was established with ice-cold 70% ethanol for 1 hour at 4°C. The ethanol was then removed, and the cells were stained for 10 minutes at room temperature with 40 mM AR-S solution. The stained portions were observed under a fluorescence microscope at light source (DM IL LED Fluo).

## Quantitative real-time PCR

Total messenger RNA (mRNA) was isolated from culture hMSCs on scaffolds and treated with OS for 5 days, and complementary deoxyribonucleic acid (cDNA) was transcribed with reverse transcriptase (Invitrogen) and oligodeoxythymidine

primers. The cDNA was amplified with TaqMan universal polymerase chain reaction (PCR) master mix (Applied Biosystems, USA) and primers and TaqMan probe sets for alkaline phosphatase (ALP; Hs01029144\_m1), osteocalcin (OC; Hs01587814\_g1), and runt-related transcription factor 2 (Runx2; Hs00231692\_m1) were purchased from Applied Biosciences. All TaqMan PCR was performed using StepOne Plus real-time PCR system (Applied Biosystems). Amount of cDNAs were normalized to that of 18S ribosomal RNA.

## Animal experiments

Six adult (over 3 months old) male New Zealand White rabbits (2.5–3.0 kg) were anesthetized with an intramuscular dose of ketamine (35 mg/kg; Yuhan, South Korea) and xylazine (5 mg/kg; Bayer Korea, South Korea), and then local anesthesia was provided using a 2% lidocaine solution. After proper preparation, three separated circular calvarial defects were made using a trephine with an outer diameter of 6 mm on a slow-speed electric hand piece while applying 0.9% physiologic saline irrigation. Each scaffold was implanted in the bone defects. One of the defects was used as a control, without implantation. The healing process was observed 1, 2, 4, and 8 weeks postimplantation, and the defects together with the surrounding bone were dissected from the host bone. Specimens were removed and placed in phosphate-buffered 4% paraformaldehyde solution (pH 7.2) inside a 4°C refrigerator for fixation (7–10 days).

## Histological analysis

The specimens were decalcified with 8% formic acid/8% HCl before being dehydrated in a graded alcohol series (70%–100%) and then embedded in paraffin. The specimens were cut into 5  $\mu$ m sections (HM 325; Microm, Germany), and five sections from the central part of each sample were stained with hematoxylin and eosin (H&E) and Goldner's Masson trichrome. New bone formation and inflammatory response were then examined under a light microscope. The system included a digital camera (DFC-480; Leica) mounted on a light microscope (DMR; Leica). Furthermore, to quantify the amount of new bone formation, the bone area was pseudocolored using Adobe Photoshop CS2, and the area was measured using Image Pro Plus software (Media Cybernetics, USA).

## Statistical analysis

All experiments were performed at least in triplicate. The values are expressed as means  $\pm$  standard deviation, and statistical analysis was performed by one-way analysis of variance followed by Student's *t*-test using Prism version 5.3

software (GraphPad Software, USA).  $P < 0.05$  was considered statistically significant.

## Results and discussion

### Morphology of SF/PCL nano/microfibrous composite scaffolds

When using nanofibrous scaffolds, it is difficult to manufacture three-dimensional structures due to the small diameter of the fibers. Therefore, there is limited cell migration to the center of the scaffold because the inside pores are too small. In contrast, microfibrous scaffolds can easily make a three-dimensional structure, but cell adhesion and proliferation on the scaffold become more difficult owing to the decrease of specific surface area caused by the large pore sizes.<sup>33</sup> Therefore, composite scaffolds containing a combination of nanofibers and microfibers were designed in this study (Figure 1). PCL microfibers play a role in the skeleton of composite scaffolds, facilitating cell infiltration by the formation of large pores. Cells can effectively adhere and grow on the composite scaffolds, because the SF nanofibers provide an ECM-like environment. The ratios of SF nanofibers and PCL microfibers were controlled by a flow-rate change of the SF solution during electrospinning. After accumulation for several hours, scaffolds with a thickness of 2–3 mm were prepared by hybrid electrospinning. Figure S1 shows the SEM images and fiber distributions of SF of the nanofibers with various electrospinning conditions, in accordance with Table 1. Despite changes in the electrospinning conditions, the average diameter of the SF/PCL 2/98 nano/microfibrous composite scaffold was similar to that of the SF/PCL 4/96 and SF/PCL 6/94 nano/microfibrous composite scaffolds. However, the SF/PCL 8/92 nano/microfibrous composite scaffold had the smallest average diameter with the largest fiber distribution, since the applied voltage was increased greatly along with the flow rate. The surface morphologies of the PCL microfibrous scaffold and SF/PCL nano/microfibrous composite scaffolds with various SF-nanofiber contents can be seen in Figure 2. It was found that the SF nanofibers and PCL microfibers were randomly deposited on the collector, and the micropores formed by PCL microfibers were split into smaller sizes by the electrospun SF nanofibers. During electrospinning, the electrostatic attraction between the needle tip and the collector was influenced by the applied voltage and the needle tip-to-collector distance (TCD). In this system, the TCD was decreased by the deposition of PCL microfibers on the collector with spinning time. To increase the SF-nanofiber content incorporated in the composite scaffolds, the applied voltage and flow rate were increased. For the same reasons, a higher quantity of SF nanofibers was deposited onto the PCL

**Figure 2** Changes in morphology of the PCL microfibrillar scaffold and SF/PCL nano/microfibrillar composite scaffolds consisting of varying SF-nanofiber content.

**Notes:** (A) PCL 100, (B) SF/PCL 2/98, (C) SF/PCL 4/96, (D) SF/PCL 6/94, and (E) SF/PCL 8/92.

**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin.

microfibers parallel to their axis. Therefore, the micropores of the SF/PCL nano/microfibrillar composite scaffolds were not blocked despite an increase of SF included in the nanofibers.

### Stabilization of SF/PCL nano/microfibrillar composite scaffolds

Water-vapor treatment is necessary for the stabilization of water-soluble SF nanofibers fabricated from regenerated SF solution. The stabilization of SF nanofibers using water vapor was reported in our previous studies.<sup>28,29</sup> SF/PCL nano/microfibrillar scaffolds were immersed in distilled water for

1 hour after water-vapor treatment, and then dried to observe changes in surface morphology (Figure S2). No morphological changes were observed in Figure S2 in comparison to Figure 2. It was found that water-vapor treatment effectively led to the stabilization of the water-soluble SF nanofibers.

### Pore properties

The properties of the pores in the SF/PCL nano/microfibrillar composite scaffolds were analyzed through mercury porosimetry. Figure 3 shows the pore distributions of the SF/PCL nano/microfibrillar composite scaffolds. It can be seen that

**Figure 3** Pore distributions of the PCL microfibrous scaffold and SF/PCL nano/microfibrous composite scaffolds consisting of varying SF-nanofiber content. **Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin.

the number of small pores in the SF/PCL nano/microfibrous composite scaffolds increased with the increment of SF-nanofiber content, as the deposited SF nanofibers divided the large pores originally formed by the PCL microfibers into smaller pores. This result is consistent with the SEM images in Figure 2. The porosity of the PCL microfibrous scaffold and SF/PCL nano/microfibrous composite scaffolds was close to 80%, irrespective of the SF-nanofiber content. These results could be explained in terms of the high surface area-to-volume ratio of the nanofibers. Therefore, increasing amounts of SF nanofiber in the composite scaffolds did not affect porosity. These results indicated that a three-dimensional scaffold with highly porous structure was successfully fabricated.

## Mechanical properties

The tensile properties were measured to analyze the mechanical properties of the SF/PCL nano/microfibrous composite scaffolds. The tensile properties are shown in Table 2 and Figure 4. The tensile strength of the composite scaffolds, excluding SF/PCL 8/92, was lower than that of the PCL microfibrous scaffold, and gradually decreased with increasing SF-nanofiber content in the composite scaffolds, due to poor interaction between the SF nanofiber and PCL microfiber. In the case of the SF/PCL 8/92 nano/microfibrous

composite scaffold, the SF nanofibers deposited onto the PCL microfibers were physically connected to the PCL microfibers, allowing SF-nanofiber membranes formed between the PCL microfibrous layers to affect tensile strength. For these reasons, the SF/PCL 8/92 scaffolds had the highest tensile strength. The tensile modulus decreased with increasing SF-nanofiber content in the composite scaffolds, because the SF nanofibers were more flexible than PCL microfiber.

## In vitro cell proliferation

Various cell tests were conducted on the PCL microfibrous scaffold and SF/PCL nano/microfibrous composite scaffolds to determine in vitro cell cytocompatibility. The proliferation of hMSCs on the PCL microfibrous scaffold and the SF/PCL nano/microfibrous composite scaffolds was evaluated on

**Table 2** Mechanical properties of SF/PCL nano/microfibrous composite scaffolds with varying SF-nanofiber content

	Tensile strength (MPa)	Elongation at break (%)	Modulus (MPa)
PCL 100	0.79±0.04	5.1±0.3	15.8±1.5
SF/PCL 2/98	0.72±0.09	7.6±0.5	9.5±1.2
SF/PCL 4/96	0.48±0.11	4.5±0.4	10.5±2.5
SF/PCL 6/94	0.54±0.11	9.2±1.2	6.3±1.2
SF/PCL 8/92	0.88±0.11	5.6±0.5	14.6±1.6

**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin.

**Figure 4** Stress–strain curves of the PCL microfibrillar scaffold and SF/PCL nano/microfibrillar composite scaffolds consisting of varying SF-nanofiber content. **Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin.

day 1, 3, 6, and 12 using an MTS assay. Figure 5 shows the MTS results at 1, 3, 6, and 12 days after cell seeding. The MTS results showed that cell proliferation of the SF/PCL 2/98 ( $0.162 \pm 0.015$ ) and SF/PCL 6/94 ( $0.139 \pm 0.007$ ) nano/microfibrillar composite scaffolds was significantly higher than that on the PCL microfibrillar scaffold ( $0.021 \pm 0.006$ ) at 1 day of cell culture ( $P < 0.05$ ). The result indicated that the addition of SF nanofibers affects initial cell adhesion. In addition, the cells gradually grew well from day 3 to 12 on both of the SF/PCL 2/98 and SF/PCL 6/94 nano/microfibrillar composite scaffolds, and the optical densities of the SF/PCL nano/microfibrillar composite scaffolds were higher than that of the PCL microfibrillar scaffold during the period of cell culture. These data indicated that cell proliferation on the scaffolds was clearly influenced by SF nanofiber in the microfibrillar composite scaffolds.

Figure 6 shows SEM images of the hMSCs on the composite scaffolds after 3 days of culturing. Cell clusters were not observed in the PCL microfibrillar scaffold, as its pore size was too large. In the case of the composite scaffolds, hMSCs adhered well and formed cell clusters, because smaller pores were made by the deposition of electrospun SF nanofibers on the PCL microfibrils. Furthermore, hMSCs were elongated and spread on the nanofibrillar surface of the composite scaffolds.

### In vitro cell viability and cytotoxicity

The viability/cytotoxicity of hMSCs on different types of scaffolds with varying SF content was visualized with fluorescence microscopy (Figure 7). Calcein AM and EthD-1 were used as Live/Dead reagents. The live cells were stained with calcein AM to emit green fluorescence under a

**Figure 5** Proliferation of human mesenchymal stem cells on the PCL 100, SF/PCL 2/98, and SF/PCL 6/94 nano/microfibrillar scaffolds evaluated by MTS assay at 1, 3, 6, and 12 days.

**Notes:** Data are represented as means  $\pm$  standard deviation of three replicates. \*Significant difference compared to cells cultured on PCL microfibrillar scaffolds.

**Figure 7** Viability/cytotoxicity staining of cells cultured on PCL 100, SF/PCL 2/98, and SF/PCL 6/94 nano/microfibrous composite scaffolds were observed at 5 days of culturing.

**Notes:** Live cells were labeled with calcein acetomethoxy (AM; green), while dead cells were labeled with ethidium homodimer (EthD)-I (red). Scale bar 200  $\mu$ m.

**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin.

fluorescence microscope. Dead cells, labeled with EthD-1, appeared in red. As seen in Figure 7, many living cells were stained on the SF/PCL nano/microfibrous scaffolds after 5 days of culturing. However, living cells were not observed on the PCL microfibrous scaffolds, due to the large size of the pores in comparison to the size of the seeded cells, as previously described. The cell viability of SF/PCL nano/microfibrous composite scaffolds was higher than the PCL microfibrous scaffold. However, there was negligible difference between the composite scaffolds. These results indicated that cell viability on the scaffolds was significantly influenced by existence of SF nanofibers in the composite scaffolds. Furthermore, EthD-1 staining revealed that all three types of composite scaffolds were not cytotoxic.

### In vitro cell infiltration

Generally, cell growth occurs on the surface of electrospun nanofibrous scaffolds,<sup>6,10-12</sup> while cells have difficulty growing on microfibrous scaffolds consisting of pores of size larger than the cells.<sup>33</sup> Cross-sectional images were measured to compare the ability of cells to infiltrate the PCL microfibrous scaffold with the ability to infiltrate the SF/PCL nano/microfibrous composite scaffolds. Figure 8 shows a cross section of a PCL microfibrous scaffold and the SF/PCL nano/microfibrous composite scaffolds after 5 days of culturing with the hMSCs. Cells penetrating the PCL microfibrous scaffold with a large pore size were rarely observed. This result agreed well with the previous test of cell viability. In contrast, the SF/PCL nano/microfibrous composite scaffolds exhibited high infiltration and ingrowth of hMSCs. These results indicated that the nanofibers in the

composite scaffolds played a positive role in cell growth and infiltration.

### Determination of osteoblast differentiation

Before the *in vivo* bone-regeneration analysis, *in vitro* mineralization ability of three scaffold types was determined by AR-S staining, which binds selectively to calcium deposits. Commonly, human MSCs can differentiate into osteoblasts, which produce calcium deposits. Therefore, the results of AR-S staining indicate the osteogenic differentiation capacity of hMSCs seeded on the scaffolds. In addition, OS treatment was used to promote the osteogenic differentiation of hMSCs in this study. Figure 9 shows the results of AR-S staining for the three scaffold types after 21 days of culturing with hMSCs. As shown in the figure, SF/PCL 6/94 nano/microfibrous composite scaffolds appeared to have the most calcium-rich phase in comparison to the PCL microfibrous scaffold and the SF/PCL 2/98 nano/microfibrous composite scaffold.

During cellular differentiation of osteoblasts, several genes, such as *ALP*, *BGLAP* (OC), and *RUNX2* were required. ALP is one of the most commonly used markers of osteogenesis, and reflects the proportion of osteogenic differentiation.<sup>34</sup> OC is a bone-specific protein that represents a good early marker for *in vitro* osteogenic differentiation.<sup>35</sup> In addition, Runx2 plays a key role in osteoblast differentiation.<sup>36</sup> Therefore, to confirm osteoblast differentiation, ALP, OC, and Runx2 were used as indicative markers for osteoblast differentiation. In this study, the gene-expression level of ALP was significantly increased in both the SF/PCL 2/98

**Figure 8** Hematoxylin-stained cross-sectional images of PCL 100, SF/PCL 2/98, and SF/PCL 6/94 nano/microfibrous composite scaffolds after 5 days of human mesenchymal stem cell (hMSC) culturing.

**Notes:** Arrows and asterisks indicate the penetrating hMSCs and PCL microfibers, respectively. Original magnification 100 $\times$ .

**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin.

**Figure 9** Osteoblast differentiation of human mesenchymal stem cells cultured on PCL 100, SF/PCL 2/98, and SF/PCL 6/94 nano/microfibrous composite scaffolds.

**Note:** After 21 days of culturing, mineralization was assayed using alizarin red sulfate staining.

**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin; OS, osteogenic differentiation stimulant.

(3.3-fold) and SF/PCL 6/94 (3.6-fold) nano/microfibrous composite scaffolds when compared with that cultured on the PCL microfibrous scaffold. The gene-expression level of OC also increased in both the SF/PCL 2/98 (1.8-fold) and the SF/PCL 6/94 (1.7-fold) nano/microfibrous composite scaffold. Furthermore, the gene expression of Runx2 was also increased in both the SF/PCL 2/98 (4.4-fold) and SF/PCL 6/94 (4.7-fold) nano/microfibrous composite scaffold. However, there was no significant difference between the SF/PCL 2/98 and SF/PCL 6/94 nano/microfibrous composite scaffolds ( $P>0.05$ ) (Figure 10). These results indicate that SF nanofiber can provide the environment for improved osteoblast differentiation.

### In vivo bone regeneration

To investigate the in vivo bone-regeneration ability of the PCL microfibrous scaffold and the SF/PCL nano/microfibrous composite scaffolds, the scaffolds were implanted in the calvarial defects of rabbits. Figure 11 shows low-magnification images of the H&E-stained histological sections at 1, 2, 4 and 8 weeks postimplantation. The control group had no implants. As seen in the figure,

in vivo bone regeneration was observed to progress from the defect edge toward the center. At 1 week, all groups showed an inflammatory reaction, formation of loose connective tissue, and weak new bone formation at the defect edges. At 2 weeks, new bone was formed at the defect

**Figure 10** Quantitative real-time polymerase chain reaction analysis.

**Notes:** Messenger ribonucleic acid (mRNA) expression of each osteoblast-marker gene was normalized to 18S, and relative expression level was normalized to PCL. Data represent means  $\pm$  standard deviation for three samples. \* $P<0.05$  and \*\* $P<0.01$  indicate significant differences from that of the PCL microfibrous scaffold.

**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin; ALP, alkaline phosphatase; OC, osteocalcin.

**Figure 11** Hematoxylin and eosin-stained histological sections after implantation at low magnification.

**Notes:** Representative histological sections show the cross section of calvarial defects with native bone at the edges after (A) 1 week, (B) 2 weeks, (C) 4 weeks, and (D) 8 weeks. Arrowheads indicate edges of the calvarial defects. Empty arrows indicate blood clots. Thin black arrow indicates new bone. Asterisks indicate remaining scaffolds. Original magnification 50 $\times$ .

**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin.

**Figure 12** Masson's trichrome-stained histological section after implantation.

**Notes:** Representative histological sections show cross sections of the defect center after (A) 1 week, (B) 2 weeks, (C) 4 weeks, and (D) 8 weeks. Note the presence of blood clots (empty red arrows), inflammatory cells (thin yellow arrows), osteoblasts (arrowheads), and remaining scaffold (asterisks). Original magnification 100 $\times$ .

**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin; NB, new bone; BV, blood vessel; CT, connective tissue.

edges of all groups, with induction of blood vessels into the defect sites. The control group (empty defect) was still filled with dense connective fibrous tissue after 4 weeks. However, in the case of SF/PCL 2/98 nano/microfibrous composite scaffolds, newly formed bone was observed at the defect center after 4 weeks. The SF/PCL 6/94 nano/microfibrous composite scaffolds demonstrated higher angiogenesis than the other groups. At 8 weeks postimplantation, bone regeneration was significantly induced by the SF/PCL nano/microfibrous composite scaffolds compared to both the control group and PCL microfibrous scaffold group. Notably, fully regenerated bone was observed in those implanted with SF/PCL 6/94 nano/microfibrous composite scaffolds. Figure S3 shows high-magnification images of the H&E-stained histological sections in the edges of host bone with different regeneration conditions. As shown in the figure, all implantation groups had higher angiogenesis and new bone formation than the control group in the calvarial defect edges after 2 weeks. At 8 weeks postimplantation, the boundary between host bone and newly formed bone could not be distinguished in any of the implantation groups. In particular, the matured new bone of lamellar structures was formed in the SF/PCL 6/94 composite scaffold group at 8 weeks. Figure 12 shows cross-sectional images of the center of the defect margin after Goldner's Masson trichrome stain. During the first 2 weeks after implantation, inflammatory cells existed in the center of the defect margin. The center of the defect margin was then filled with connective tissue. On the other hand, inflammation reactions disappeared and new bones were formed in the center of the defect margin at 4 weeks postimplantation. At 8 weeks, the newly formed bones in the SF/PCL 6/94 nano/microfibrous composite scaffolds were difficult to distinguish from the host bone. Bone regeneration and angiogenesis at the center of the defect margin were markedly increased with the use of SF/PCL composite scaffolds compared to both the control and the PCL microfibrous scaffold during the total regeneration period. In addition, as shown in Figure 13, the quantitative analysis of new bone area showed that a large amount of new bone was formed in the SF/PCL 6/94 nano/microfibrous composite scaffold-implanted group. These quantitative data were similar to those found by histological slide images. Consequently, these results indicated that a composite structure consisting of nanofibers and microfibers plays a positive role in bone regeneration, helping to form new bone in defect sites. As a result of the *in vivo* bone-regeneration tests, it was found that

**Figure 13** Quantitative analysis of new bone area at 8 weeks.

**Notes:** The new bone area was calculated from the histological image using Image Pro Plus software. \* $P < 0.05$  versus empty; # $P < 0.05$  versus PCL; ζ $P < 0.05$  versus SF/PCL 2/98.

**Abbreviations:** PCL, poly( $\epsilon$ -caprolactone); SF, silk fibroin.

nano/microfibrous composite scaffolds have the potential for use in bone-regeneration applications.

## Conclusion

In this study, SF/PCL nano/microfibrous composite scaffold were fabricated via hybrid electrospinning method. The SF/PCL nano/microfibrous composite scaffolds were prepared by different amounts of inclusion of SF nanofiber onto the PCL microfiber. The increment of SF nanofiber content in the composite scaffolds led to a decrease in pore size. Results from MTS assay, SEM images of hMSC-seeded scaffolds, and viability tests indicated that it had no significant difference on cell growth and pore size in the case of composite scaffolds. However, composite scaffolds are excellent than PCL microfibrous scaffolds. This means that small pores formed by SF nanofibers in composite scaffolds have a positive effect on cell growth. Therefore, the SF/PCL nano/microfibrous composite scaffold provides a suitable environment for hMSC proliferation, adhesion, and differentiation into osteoblasts *in vitro*. In addition, the SF/PCL nano/microfibrous composite scaffolds stimulated new bone formation in rabbit calvarial defect model *in vivo*. Our findings suggest that SF/PCL nano/microfibrous composite scaffolds have potential for use in bone-regeneration fields.
