Abstract. Where are all the semantic Web services today? In this paper, we report on preliminary quantitative results of searching the surface Web and the prominent citeseer archive as one element of the deep Web for publicly accessible semantic Web service descriptions written in OWL-S, WSML, WSDL-S or SAWSDL by means of the specialized meta-search engine Sousuo 1.6.

1 Introduction

The common user of the Web might ask: Where are all the semantic Web services in the Web today? According to a focused search conducted in January, November and December 2007 with a specialized meta-search engine Sousuo, there are not more than one hundred semantic Web service descriptions accessible in the shallow Web. This quantity appears tiny compared to the more than half million RDF sources indexed by the semantic Web search engine Swoogle, and several hundreds of Web service descriptions in WSDL found by Sousuo 1.6.

Of course, one can argue that this low number of public semantic Web services comes at no real surprise for two reasons. First, semantic Web service technology with a standard, SAWSDL, announced just recently (in August 2007), is still considered immature which provides insufficient common ground supporting its exploitation by potential end users. Independent from this (WSDL became official recommendation of the W3C in June 2007), one could have expected the massive research and development activities of the community around the globe in the past ten years to have produced a considerable amount of publicly visible semantic Web service descriptions that are not merely stored in internal project repositories.

Second, one might argue that it is not clear whether the surface Web and academic publications are the right place to look for semantic Web services, as many of them would be intended for internal or inter-enterprise use but not visible for the public. Though this is one possible reason of the low numbers reported above, there is no experimental evidence in favor of, or against this claim yet.

Thus, we conducted an initial search experiment to obtain preliminary answers to the following questions: How many semantic Web service descriptions
are actually accessible to everyone searching the Web for them? How many of these descriptions are written in the standard SAWSDL, and the non-standard OWL-S or WSML? What is the distribution of their geographic locations and application domains? How many of these service descriptions are syntactically valid, and are grounded in standard Web service technology for their principled execution in practice? Finally, how many links to semantic Web service descriptions can only be found in academic publications such as those in the prominent scientific archive citeseer as one element of the deep Web?

In this paper, we provide preliminary answers to these questions based on our limited search experiments. In particular, we restricted our first search experiments on semantic Web service descriptions independent from whether they are grounded in actually deployed WSDL services, or not. This is part of future work but should not distract from the original questions above.

The meta-search engine Sousuo with which the search has been performed together with its testing environment are described in section 2. In section 3, we provide the performance of both the search engine and its topic crawler followed by the preliminary results of our experiment in section 4, while section 5 concludes this paper.

2 Meta-search engine Sousuo

The purpose of the specialized meta-search engine Sousuo for semantic Web services is to search the surface Web and the scientific archive citeseer for semantic Web service descriptions in OWL-S, WSML, WSDL-S and SAWSDL.

2.1 Architecture

The general architecture of Sousuo is shown in figure 1.

Overview. Users may select any combination of the following search methods of Sousuo to search for semantic Web services.

- Meta-search (MS) through most prominent search engines Google with A9,
- Sousuo’s own focussed topic crawler (TC) based on the WebSphinx crawler,
- Inverse ontology based search (IOS) via Swoogle, and
- Full text scientific archive search (FTAS).

Sousuo considers returned links to syntactically valid service descriptions relevant. For validation, Sousuo uses the validators of publicly available OWL-S API, WSMO4J API, and SAWSDL4J API. Depending on the validation result, it determines the relevance ranking score of each link, that is a score of 1.0 if the service description is syntactically valid, 0.5 if validation failed due to minor syntax errors, and 0 else. Validation is complemented by checking whether the link has been already stored in the local database (Open Berkeley XML database[4]).

This database can be queried and evaluated by the user according to the distribution of geographic locations, description formats, domains and categories
of semantic Web services, as well as the coverage of the total result returned for any combination of the different search methods. Sousuo 1.4 also informs about the actual performance of both its topic crawler and the whole meta-search engine. Sousuo has been implemented in Java and is publicly available through the software portal semwebcentral.org dedicated to semantic Web software.

**Meta-search and topic crawler.** The meta-search of Sousuo is restricted to querying Google, Swoogle, and A9 through their API with predefined and user given search keys. Predefined search keys focus on links to files of type, for example, filetype:\{wsdl sawsdl, wsml wsml, owls service, owls profile, owl jp, owl kr, owl tw, owl cn, owl service Profile, owl profile, wsdl annotation \}. This is complemented by a simple focussed topic crawler which performs a recursive depth-first search taking the continuously growing set of (initially given) links in the local database as root and base set, and terminates with a time-out or given maximum of search depth reached. Validation, ranking, and redundancy checking of found links are as described above.

**Inverse ontology based search.** This search method is looking for services that reuse ontologies imported by services that have been already located by Sousuo. For this purpose, Sousuo first checks for each link to a service stored in the database the assigned set of individual ontologies required to understand its semantics. It then searches for service descriptions that contain one or multiple of these selected ontology links through respective queries to Swoogle, A9 and Google. The intuition behind this inverse ontology based search is that semantic Web services share ontologies but may not be fully indexed.

**Full text archive search.** Sousuo queries the scientific archive citeseer via its API for references to papers on semantic Web services, retrieves the respective documents in the answer set formatted in pdf, and scans each of them for embedded relevant links to SWS descriptions. These links then get validated, ranked, checked for redundancy, and stored in the local database by Sousuo as mentioned above.
Querying the local database. Finally, Sousuo allows the user to search for relevant semantic Web services in its local database by means of full text and structured XML based search as shown for the latter case in figure 2.

**Fig. 2.** Structured search of Sousuo’s local XML index of semantic Web services.

### 2.2 Testing environment

**Search period and hardware.** We ran our search experiment from January 1, 2007, to July 25, 2007, and November 2007, by executing Sousuo once every two weeks over 24 hours on a notebook with CPU Intel Core 2 Duo 2.0GHZ, 2GB RAM, and LAN 10 Mbit/s access to the Internet.

**Search space and index.** Sousuo does not search any surface Web directory such as Yahoo. In fact, respective experiments showed that their answer sets were covered by the one of Sousuo. However, we are currently working to enlarge the search space of Sousuo by incorporating search engines claiming to provide access to parts of the deep Web such as clusty, intute, and infomine with an open, non-commercial API for inquiries.

Hence, the search space of Sousuo is the union of the indices of queried search engines, the discovered realm of the focussed topic crawler plus the index of the scientific archive citeseer. This size is, in general, impossible to determine accurately due to the privacy of information on size, redundancy, and overlapping (coverage). However, the size of the index of Google is estimated with 11.3 billion links, while the size of the Swoogle index and citeseer archive is estimated with

1 at [http://www.linksandlaw.de/news234-indexgroesse.htm](http://www.linksandlaw.de/news234-indexgroesse.htm)
1.7 million \(^2\), and 767,558 links, respectively. Besides, our focussed topic crawler explored 11.2 million links in total during the experiment. With an admittedly speculative 90\% of an overlap of the latter indices with the Google index, the search space of Sousuo might be estimated with 13 billion pages. The current size of Sousuo’s index equals that of its total answer set for the whole search experiment which amounts to 1439 non-redundant, validated links stored in the local database.

3 Performance

As the real relevance set of semantic Web services in the Web is unknown, and impossible to deduce from neither the set of crawled pages nor the answer sets of particular sources queried, we approximate the performance measures of precision and recall for the topic crawler by means of target recall and target precision as defined in figure 3 according to [5].

![Fig. 3. Target precision and recall.](http://swoogle.umbc.edu/index.php?option=com-swoogle-stats)
3.1 Performance of focussed topic crawler

Figure 4 shows the average target precision and recall of the focussed topic crawler of Sousuo. It explored around 11.2 million links in total with fairly reasonable throughput of 46 links per minute during the experiment. Regarding its focussed search the target precision is comparably fair enough as well [5].

![Graph showing precision and recall over pages crawled](image)

Fig. 4. Average target precision and recall of Sousuo’s focussed topic crawler.

3.2 Performance of Sousuo

For measuring the precision of the search engine Sousuo, we determine the classical ratio between the size of the intersection of its answer set $AS$ with the relevance set $RS$ and the size of $AS$. The answer set of Sousuo equals the set of valid links taken from those returned by its topic crawler, the search using Google and A9 API which answer set is limited to 1k, respectively, 10k links per day, the inverse ontology based search via Swoogle, and the full text search through citeseer. The relevance set, however, is restricted to the subset of (manually
determined) relevant links of the total union of answer sets produced during the search period.

**Fig. 5.** Average local precision and recall of Sousuo.

Figure 5 displays the fairly high average local precision and recall of Sousuo while its target precision and recall is shown in figure 6.

**Fig. 6.** Average target precision and recall of Sousuo.

### 4 Experimental results

The total number of semantic Web services in OWL-S, WSML, WSDL-S and SWASDL including the test collections amounts to 1439 of which only about four percent (65 services) are available outside these collections in the surface
Web and through citeseer. Figure 7 shows the number of relevant links found by each of the individual search methods of Sousuo without redundancy checking and test collections OWLS-TC2 [2] and SWS-TC [3]. These quantities did not change as a result of our final search run in December (67 semantic Web services, and 600 non-redundant WSDL services found in December).

</table>

The overlapping of answer sets from individual search methods of Sousuo for those services not included in the above mentioned test collections is summarized in table 1. It shows, for example, that the full text archive search returned valid links to semantic Web services in the archive citeseer that were not returned by Google and A9, and a few that have not been returned by any other method. Despite its functional simplicity, the same result holds with our focused topic crawler. This is in contrast to the inverse ontology based search which answer set is completely covered by those of the other search methods.
4.1 Distribution of semantic Web service formats

Figure 8 shows the distribution of semantic Web service descriptions in prominent formats, that are OWL-S, WSML, WSDL-S and SAWSDL.

![Pie chart showing distribution of prominent semantic Web service formats](image)

**Fig. 8.** Distribution of prominent semantic Web service formats.

Given the historic evolution of the field, and its reasonably fair software support, it comes at no surprise that the quantities of semantic Web service descriptions in OWL-S outnumber the considered alternatives. Remarkably, there are less public WSML services than for WSDL-S and SAWSDL together. Though SAWSDL became a proposed recommendation by the W3C just recently, its software support worldwide still appears comparatively negligible which might rapidly change in near term. Apart from two rather medium sized SWS retrieval test collections for OWL-S, that are the OWLS-TC2 [2] and the SWS-TC[3], we did not find any other collection in the Web.

4.2 Geographic distribution

Figures 9 and 10 provide an overview of the geographic distribution and locations of the publicly accessible semantic Web services. Regarding the history of the semantic Web vision, in particular the early joint start between researchers in the US and the EU on DAML+OIL, OWL and OWL-S, as well as the massive funding of WSMO related projects in this field by the European Commission, it might not come at a surprise that, according to the quantities reported, the
domain appears clearly dominated by the US and Europe while being remarkably close to each other.

However, what surprised us most is that, though major projects in the area exist, we could not find any valid semantic Web service description published in the rest of the world publicly, in particular the Asia and Pacific rim. Additional personal communication with few selected research groups at universities in these regions revealed that, if semantic Web service descriptions do exist at their site, the public retrieval from specific project related repositories is prohibited, hence invisible to any search engine. In general, we appreciate any reference by the interested reader to publicly accessible semantic Web services in one of the considered formats, in particular if published in the above mentioned geographic regions.

4.3 Internet domains and business categories

Figures 11 and 12 show the distribution of the domain and business category of found services outside the test collections. Business and travel are the most common categories, followed by finance and education.

In compliance with the prevalent geographic distribution and location of semantic Web service links in the US and the EU, the majority of links from Internet domains devoted to commerce (.com, 8%), organisational (.org, 28%) and
educational institutions (.edu, 15\%) is hosted in these world regions. Remarkably, most of these semantic Web services publicly accessible in the EU are located in the UK.

The most common business domain for semantic Web services according to their naming or statement in the profiles are business (16\%) and travel (17\%), followed by education (11\%), finance (11\%), and government (6\%). One third of found semantic Web service links, however, belongs to a variety of other domains of smaller size such as sports and health.

5 Conclusions

The preliminary results of our experimental searching for semantic Web services in the surface Web by use of a specialized meta-search engine is rather desillusioning. We found not more than around 1500 indexed semantic service descriptions in OWL-S, WSML, WSDL-S or SAWSDL in the Web, of which only about four percent are located outside special test collections like the OWLS-TC2. This quantity appears tiny compared with the sheer volumes of estimated thirty billion and one million indexed resources in the Web, respectively, semantic Web encoded in RDF and OWL.

As mentioned above, the reported preliminary experimental result does not reflect the strong research efforts carried out in the SWS domain world wide in the past few years, independent from the status of maturity of SWS technology and implied low adoption by end users yet. Nevertheless, the result might encourage the community as a whole to increase its visibility and awareness to
the common Web user outside the community and savvy project teams also by publishing a significant number of SWS show cases in the surface Web.

Although one could have expected these results, in particular the majority of semantic Web services being published in protected internal project repositories and other sites of the deep Web[6], there was no experimental evidence available in favor of this claim or against. On the other hand, there still is plenty of space left to search both the surface and the deep Web: The search space of Sousuo in its current version is limited to only few selected indices of freely accessible and prominent search engines with open API, that are Google, A9, Swoogle, and the scientific archive citeseer.

However, raising awareness by a significant number of show cases seems senseless if it is not complemented by community efforts to equip end users with easy to use software support for building, sharing and reusing semantic Web services. Unfortunately, this is support is missing either, despite the variety of SWS related software available at relevant open source software portals such as semwebcentral.org and sourceforge.net. Though, it remains to be seen whether and to what extent these tools or the experience of developing them can be exploited to support the standard SAWSDL for which, apart from the project internal MWSDI infrastructure and Lumina search engine, no public software support exists yet. Sousuo is available at http://projects.semwebcentral.org/projects/sousuo/

Ongoing work is on improving the search methods of Sousuo for an updated version 2.0.
