

Rare Occurrence of Extradigital Glomangioma in the Prepatellar Bursa of a 40-Year-Old: A Case Study

Dylan C Crawford¹, Michael O'Malley¹, Linsen T Samuel¹

Learning Point of the Article:

The learning point of the article is to maintain a broad differential when there is no clear obvious diagnosis.

Abstract

Introduction: A solitary subcutaneous mass can be a common clinical finding for patients symptomatic for knee pain, especially when direct pressure by kneeling on the anterior aspect of the knee causes pain.

Case Report: We present a 40-year-old who noticed a small fluid filled mass that has become progressively larger and more painful over the past 7 years. The patient's primary complaint was sharp pain with direct contact. Ultimately, a surgical excision was performed to remove the mass. The histopathological report came back as a glomangioma, a subtype of a glomus tumor. To the best of our knowledge, this is the youngest reported case of a glomangioma of the knee.

Conclusion: Glomus tumors found on the digital and subungual regions of patients are a common clinical finding. An extradigital occurrence of a glomangioma, a subtype of a glomus tumor, is rarely found, especially in younger patients. Therefore, a histopathological examination must be done after the removal of any subcutaneous mass.

Keywords: Glomus tumor, glomangioma, knee pain, subcutaneous mass, case study.

Introduction

Knee pain as a result of a solitary subcutaneous mass can be a common clinical finding. Those localized over the anterior aspect of the knee can prove to be more symptomatic as they see direct pressure when kneeled on. Common knee masses are aseptic bursitis, ganglia cysts, and lipomas [1, 2, 3]. They are often treated conservatively but for those that provoke significant pain, surgical excision can be considered [4].

Case Study

A 40-year-old was seen for a yearly physical, at one of our institution's primary care facilities. He was found to have

prepatellar fluid collection on the anterior aspect of the left knee with pain when kneeled on and with direct palpation. His primary care provider noted it as possible bursitis and referred the patient to our orthopedics center for further evaluation.

During the orthopedic evaluation, the patient presented with a small bump on the anterior of his left knee that had recently increased in size. The patient stated extreme sensitivity to touch not allowing him to put direct pressure on this area. A thorough physical examination showed that there was no evidence of infection, warmth to touch, and seemed fluid filled. He exhibited a painless arc of motion, no pain with weight bearing, and no signs of mechanical instability.

X-ray imaging revealed no foreign body and no joint or bone

Figure 1: W KNEE AP Left. AP, lateral, and sunrise view of the left knee. Joints bases are well preserved without significant osteoarthritis. No fractures, dislocation, or loose body seen. Subtle anterior subcutaneous soft-tissue mass appreciated on sunrise and lateral views without evidence of foreign body or calcification noted. Arrows point toward the glomangioma.

Figure 2: W KNEE LAT left. AP, lateral, and sunrise view of the left knee. Joints bases are well preserved without significant osteoarthritis. No fractures, dislocation, or loose body seen. Subtle anterior subcutaneous soft-tissue mass appreciated on sunrise and lateral views without evidence of foreign body or calcification noted. Arrows point toward the glomangioma.

Figure 3: X KNEE SUNRISE Left, AP, lateral, and sunrise view of the left knee. Joints bases are well preserved without significant osteoarthritis. No fractures, dislocation, or loose body seen. Subtle anterior subcutaneous soft-tissue mass appreciated on sunrise and lateral views without evidence of foreign body or calcification noted. Arrows point toward the glomangioma.

Figure 4: Histopathological findings showed no presence of AE1/AE3 on immunohistochemical staining (AE1/AE3 10x).

pathology. Considering the size, location, and benign features of the mass, further imaging was not felt indicated. The patient was diagnosed with a 1 cm × 1 cm fluid filled subcutaneous mass over the anterior aspect of the inferior pole patella. Conservative and operative treatment options to remove the mass were suggested. Considering the amount of sensitivity, the patient was experiencing, the decision to proceed with surgical excision was made.

An open excision under local anesthesia was performed to remove a small palpable soft-tissue mass of the patients left knee. Gross inspection revealed a small, bluish-tinged, and fluid filled cystic structure. Histopathologic examination revealed a vascular neoplasm in cross-section dominated by bland-appearing oval cells. Immunochemical stains were positive for smooth muscle actin and synaptophysin and negative for chromogranin, S-100 protein, and melanoma antigens. This is consistent with a glomangioma.

At their most recent post-operative follow-up, the wound was healed with no evidence of infection or reoccurrence. The patient denied any residual tenderness or pain and was symptom free.

Discussion

Glomus tumors were first depicted by Masson in 1924 as a benign tumor with morphologically distinct features [5]. They are rare and only constitute for <1.6% of all benign soft-tissue extremity tumors [6]. Histologically, there are three subtypes of glomus tumor: Solid glomus tumor, glomangioma and glomangiomyoma [7]. Roughly 73% of all these tumors occur in the upper extremities, with most found in the subungual regions [8]. Extradigital glomus tumors are rarely found in atypical regions such as the kidney, liver, lung, and oral cavity [8, 9, 10, 11]. They can also be found in the lower extremity [12, 13]. Lower extremity presentations of glomangioma tend to present in older adults, thereby mimicking osteoarthritis symptoms which tends to be a common complaint in this demographic. However, our patient was diagnosed with glomangioma at 40 years old, with complaints since the age of 33. Three common symptoms of sensitivity to cold, palpation pain, and paroxysmal help identify a glomus tumor [14]. In a case study of 51 patients, 29% presented a blue discoloration and 33% presented a pulp nodule [15].

Figure 5: Chromogranin 10x Histopathological findings showed no presence of chromogranin on immunohistochemical staining.

Figure 6: Histopathological findings showed no presence of H&E on immunohistochemical staining: (a) Lower magnification, (H&E 5x) and (b) higher magnification, (H&E 20x).

Figure 7: Histopathological findings showed no presence of MelanA on immunohistochemical staining (MelanA 10x).

Figure 8: Histopathological findings showed no presence of s100 on immunohistochemical staining (s100 10x).

Figure 9: Histopathological findings showed an abundant presence of smooth muscle actin (SMA) on immunohistochemical staining (SMA 10x).

Figure 10: Histopathological findings showed a slight presence of Synaptophysin on immunohistochemical staining: (a) Lower magnification, (Synaptophysin 10x) and (b) higher magnification, (Synaptophysin 40x).

Conclusion

Solitary subcutaneous masses are a common clinical finding, but often require further examination to determine the underlying pathology. Glomus tumors are often found in patients with pain on palpation and are mainly found in the digital and subungual regions. An extradigital occurrence of a glomangioma, a subtype of a glomus tumor, is rarely found, especially on younger patients. Therefore, a histopathological examination must be done after the removal of any subcutaneous mass.

Clinical Message

Diagnosing the pathology of a small subcutaneous mass can prove challenging. There are many possible differential diagnoses, which is why a histopathological examination following the surgical removal must be done.

Knee pain caused by a glomus tumor is a rare occurrence and is often miss diagnosed [14, 15]. A case study at the University of Florida reported that a patient attempted to have a cyst in the superficial soft tissue of their patella removed. Prolonged bleeding led them to being admitted into the emergency department. Further imaging and a biopsy determined that the mass was a glomangioma and a surgical excision was performed [6]. Another case study in Greece treated a patient for 2 years for chondromalacia of the patella before the patient exhibited walking pain. An ultrasound and MRI confirmed a mass and a surgical excision was performed. Following the operation, histopathologic examination revealed a glomangioma [16].

Out of the three common symptoms of a glomus tumor, our patient only presented pain on palpation. In this case, the mass was felt to be subcutaneous and fluid filled, such as a small benign cyst or ganglion [Figure 1-3], and considering the sensitivity to touch the patient was experiencing, it was felt safe to exercise. The histopathologic report showed the presence of round appearing oval cells and smooth muscle actin, which are consistent with a glomangioma [Figure 9]. On immunochemical staining, synaptophysin was present [Figure 10]. Other possible diagnoses were ruled out by examining the remaining stains [Figures 4-8]. There are case reports presenting synaptophysin in atypical visceral locations such as the pancreas and liver, but very few reporting its presence in the lower and upper extremities [17, 18]. A glomus tumor is a rare cause of knee pain, but if a subcutaneous mass possesses the characteristics as described above, especially extreme sensitivity to touch, it should be considered in the differential diagnosis.

Declaration of patient consent: The authors certify that they have obtained all appropriate patient consent forms. In the form, the patient has given the consent for his/ her images and other clinical information to be reported in the journal. The patient understands that his/ her names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.
