Abstract. More than 30 years after their inception, the decidability proofs for reachability in vector addition systems (VAS) still retain much of their mystery. These proofs rely crucially on a decomposition of runs successively refined by Mayr, Kosaraju, and Lambert, which appears rather magical, and for which no complexity upper bound is known.

We first offer a justification for this decomposition technique, by showing that it computes the ideal decomposition of the set of runs, using the natural embedding relation between runs as well quasi ordering. In a second part, we apply recent results on the complexity of termination thanks to well quasi orders and well orders to obtain a cubic Ackermann upper bound for the decomposition algorithms, thus providing the first known upper bounds for general VAS reachability.

Keywords. Vector addition system, reachability, well quasi order, ideal, fast-growing complexity

1. Introduction

Vector addition systems (VAS), or equivalently Petri nets, find a wide range of applications in the modelling of concurrent, chemical, biological, or business processes. Their algorithmics, and in particular the decidability of their reachability problem, is a central component to many decidability results spanning from the verification of asynchronous programs [15] to the decidability of data logics [4, 10, 8]. Considered as one of the great achievements of theoretical computer science, the original [1981] decidability proof of Mayr [34] is the culmination of more than a decade of research into the topic, and builds notably on an incomplete proof by Sacerdote and Tenney [38]. The proof was simplified a year later by Kosaraju [24]; see also the account by Müller [35] and the self-contained and detailed monograph of Reutenauer [37] on this second proof. In spite of this success, as put by Lambert [26] “the complexity of the two proofs (especially in [34]) wrapped the result in mystery and no use of their original ideas” was made before he provided a further simplification ten years later in [1992], and employed it to prove results on VAS languages.

At the heart of the various proofs lies a decomposition technique, which we dub the Kosaraju-Lambert-Mayr-Sacerdote-Tenney (KLMST) decomposition in this article after its inventors. In a nutshell, the KLMST decomposition defines both a structure and a condition for this structure to represent in some way the set of all runs witnessing reachability. The algorithms advanced by Mayr, Kosaraju, and Lambert compute this decomposition by...
successive refinements of the structure until the condition is fulfilled. The KLMST decomposition is a powerful tool when reasoning about VAS runs, and it has notably been employed:

- by Habermehl, Meyer, and Wimmel [17] to show that the downward-closure of a labelled VAS language is effectively computable—let us mention a new proof by Zetzsche [44], which does not explicitly rely on the KLMST decomposition—, and
- by Leroux [29] to derive a new algorithm for reachability based on Presburger inductive invariants—he would later re-prove the correctness of this new algorithm without referring to the KLMST decomposition, yielding a compact self-contained decidability proof for VAS reachability [30].

Our feeling however is that the decidability of VAS reachability, and especially the KLMST decomposition, is still shrouded in mystery. The result is highly complex on two accounts:

On a conceptual level the various instances of the KLMST decomposition seem rather magical. How did Mayr come up with regular constraint graphs with a consistent marking? How did Kosaraju come up with generalised VASS and his θ condition? How did Lambert come up with his perfect condition on marked graph-transition sequences? Most importantly, which guidelines to follow in order to develop similar concepts for VAS extensions where the decidability of reachability is still open, e.g. for unordered data Petri nets [28], pushdown VASS [27], or branching VAS [39]?

Arguably, the issue here is not to understand how these structures and conditions are used in the algorithms themselves, nor to check that they indeed yield the decidability of VAS reachability. Rather, the issue is to explain how these structures and conditions can be derived in a principled manner.

On a computational complexity level no complexity upper bound is known for the general VAS reachability problem, while the best known lower bound is ExpSpace-hardness [32]. The only known tight bounds pertain to the very specific case of 2-dimensional VAS with states, which were recently shown to have a PSPACE-complete reachability problem [3].

As observed e.g. by Müller [35] the algorithms computing the KLMST decomposition are not primitive-recursive, but no one has been able to derive a complexity upper bound for these algorithms, while the new algorithm of Leroux [29, 30] using Presburger inductive invariants seems even harder to analyse from a complexity viewpoint.

Our contributions in this paper are first to propose an explanation for the KLMST decomposition. Using a well quasi ordering of VAS runs defined by Jančar [20] and Leroux [30] and recalled in Section 5, we show a Decomposition Theorem (Theorem 8.1): the KLMST algorithm computes an ideal decomposition of the set of runs, i.e. a decomposition into irreducible downward-closed sets (see Section 8). The effective representation of those ideals through finite structures turns out to match exactly the structures.
and conditions expressed by Lambert [26], see sections 6 and 7. This provides a full formal framework in which the reachability problem in various VAS extensions might be cast, offering some hope to see progress on those open issues.

The second contribution in Section 9 is the proof of a “cubic Ackermann” complexity upper bound on the complexity of the KLMST decomposition algorithm, i.e., an $F_{\omega 3}$ upper bound in the fast-growing complexity hierarchy $(F_\alpha)_\alpha$ defined in [41]. We apply to this end the recent results on bounding the length of controlled bad sequences over well quasi orders from [42, 40]. It yields the first known upper bound on VAS reachability. As a byproduct, it also yields the first complexity upper bound for numerous problems known decidable thanks to a reduction to VAS reachability, e.g. [4, 15, 10, 8] among many others.

We start in sections 2, 3, and 4 by presenting the necessary background on VAS, well quasi orders, and ideals.

2. Vector Addition Systems

Vectors and sets of vectors in $\mathbb{Z}^d$ for some natural $d$ are denoted in bold face. A **periodic set** is a subset $P$ of $\mathbb{Z}^d$ that contains the zero vector $0$ and such that $p + q \in P$ for all $p, q \in P$.

A **vector addition system** of dimension $d$ in $\mathbb{N}$ is a finite set $A$ of actions $a$ in $\mathbb{Z}^d$ [23]. The operational semantics of VASs operates on configurations, which are vectors $c$ in $\mathbb{N}^d$. A **transition** is then a triple $(u, a, v) \in \mathbb{N}^d \times A \times \mathbb{N}^d$ such that $v = u + a$, where addition operates componentwise; the set of transitions of $A$ is denoted by $\text{Trans}_A$.

A **prerun** over $A$ is a triple $\rho = (u, w, v)$ where $u$ and $v$ are two configurations in $\mathbb{N}^d$ and $w$ is a sequence of triples $(u_1, a_1, v_1) \cdots (u_k, a_k, v_k)$ in $(\mathbb{N}^d \times A \times \mathbb{N}^d)^*$. The configurations $u$ and $v$ are called respectively the **source** and **target** of $\rho$, and are denoted respectively by $\text{src}(\rho)$ and $\text{tgt}(\rho)$. The action sequence $\sigma = a_1 \cdots a_k$ is called the **label** of $\rho$. We write $\text{PreRuns}_A$ for the set of preruns over $A$.

A prerun $(u, w, v)$ is **connected** if $w = (u_1, a_1, v_1) \cdots (u_k, a_k, v_k)$ is a transition sequence in $\text{Trans}_A^*$ such that

- either $w = \varepsilon$ is the empty sequence and then $u = v$,
- or $k > 0$ and $u = u_1$, $v = v_k$, and $u_{j+1} = v_j$ for all $0 \leq j < k$.

We call a connected prerun $\rho$ a run. If there exists a run $\rho$ from source $u$ to target $v$ labelled by $\sigma$, we denote by $u \xrightarrow{\sigma} v$ this unique run $\rho$. Notice that it implies $v = u + \sum_{j=1}^{k} a_j$; note however that given $u$, $v$, and $\sigma$, $v = u + \sum_{j=1}^{k} a_j$ does not necessarily imply that $u \xrightarrow{\sigma} v$.

We are interested in this paper in the following decision problem:

**Problem:** VAS Reachability.

**input:** A VAS $A$, a source configuration $x$, and a target configuration $y$.

**question:** $\exists \sigma \in A^*.x \xrightarrow{\sigma} y$?
Given two configurations $x$ and $y$ in $\mathbb{N}^d$, we define the set of runs of $A$ from $x$ to $y$ as

$$\text{Runs}_A(x, y) \overset{\text{def}}{=} \{ x \xrightarrow{\sigma} y \mid \sigma \in A^* \}. \quad (1)$$

The VAS reachability problem can then be recast as asking whether the set $\text{Runs}_A(x, y)$ is non empty.

### 3. Well Quasi Orders

A quasi-order (qo) is a pair $(X, \leq)$ where $X$ is a set and $\leq$ is a reflexive and transitive binary relation over $X$. We write $x < y$ if $x \leq y$ but $y \not\leq x$. Given a set $S \subseteq X$, we define its upward-closure $\uparrow S \overset{\text{def}}{=} \{ x \in X \mid \exists s \in S. s \leq x \}$ and downward-closure $\downarrow S \overset{\text{def}}{=} \{ x \in X \mid \exists s \in S. x \leq s \}$. When $S = \{s\}$ is a singleton, we write more succinctly $\uparrow s$ and $\downarrow s$. An upward-closed set $U \subseteq X$ is such that $U = \uparrow U$ and a downward-closed set $D \subseteq X$ such that $D = \downarrow D$. Observe that upward- and downward-closed sets are closed under arbitrary union and intersection, and that the complement over $X$ of an upward-closed set is downward-closed and vice versa.

#### 3.1. Characterisations.

A finite or infinite sequence $x_0, x_1, x_2, \ldots$ of elements of a qo $(X, \leq)$ is good if there exist two indices $i < j$ such that $x_i \leq x_j$, and bad otherwise. A well quasi order (wqo) is a qo with the additional property that all its bad sequences are finite.

**Example 3.1 (Finite sets).** As an example, a set $X$ ordered by equality is a wqo if and only if it is finite: if finite, by the pigeonhole principle its bad sequences have length at most $|X|$; if infinite, any enumeration of infinitely many distinct elements yields an infinite bad sequence. \hfill \Box

There are many equivalent characterisations of wqos \cite{25, 12}. For instance, $(X, \leq)$ is a wqo if and only if it is well-founded, i.e. there are no infinite descending sequences $x_0 > x_1 > \cdots$ of elements from $X$, and it has the finite antichain (FAC) property, i.e. any set of mutually incomparable elements from $X$ is finite.

**Example 3.2 (Well orders).** Any well-founded linear order, i.e. where $\leq$ is furthermore antisymmetric and total, is a wqo: in that case, antichains have cardinal at most one. Examples include $(\mathbb{N}, \leq)$ the set of natural numbers, i.e. the ordinal $\omega$. \hfill \Box
We will also be interested in the following characterisation:

**Fact 3.3** (Descending Chain Property). A qo $(X, \leq)$ is a wqo if and only if any non-ascending chain $D_0 \supseteq D_1 \supseteq D_2 \supseteq \cdots$ of downward-closed subsets of $X$ eventually stabilises, i.e. there exists a finite rank $k$ such that $\bigcap_{i \in \mathbb{N}} D_i = D_k$.

**Proof.** For the direct implication, assume that there exists a non-ascending chain that does not stabilise, i.e. there exists an infinite descending sub-chain $D_i \supseteq D_j \supseteq D_k \subseteq \cdots$. This means that there exists an infinite sequence of elements $x_{i_j} \in D_{i_j} \setminus D_{i_{j+1}}$. Note that, if $j < k$, then $x_{i_j}$ is in $D_{i_j} \setminus D_k$, hence $x_{i_j} \not\leq x_{i_k}$, and therefore $(X, \leq)$ is not a wqo.

Conversely, consider any infinite sequence $x_0, x_1, \ldots$ of elements of $X$. Let then $U_i \defeq \bigcup_{j \leq i} \uparrow x_j$ and $D_i \defeq X \setminus U_i$. Observe that if the non-ascending chain of $D_i$’s stabilises at some rank $k$, then $U_k = U_{k+1} = U_k \cup \uparrow x_{k+1}$, hence there exists $i \leq k$ such that $x_i \leq x_{k+1}$, showing that $(X, \leq)$ is a wqo. \qed

Another consequence of the definition of wqos is:

**Fact 3.4** (Finite Basis Property). Let $(X, \leq)$ be a wqo. If $U \subseteq X$ is upward-closed, then there exists a finite basis $B \subseteq U$ such that $\uparrow B = U$.

3.2. **Elementary Operations.** Many constructions are known to yield new wqos from existing ones. In this paper we will employ the following elementary operations:

3.2.1. **Cartesian Products.** If $(X, \leq_X)$ and $(Y, \leq_Y)$ are wqos, then their Cartesian product $X \times Y$ is well quasi ordered by the product (quasi-) ordering defined by $(x, y) \leq (x', y')$ if and only if $x \leq_X x'$ and $y \leq_Y y'$. For instance, vectors in $\mathbb{N}^d$ along with the product ordering form a wqo. This result is also known as **Dickson’s Lemma.**

3.2.2. **Finite Sequences.** If $(X, \leq_X)$ is a wqo, then the set $X^*$ of finite sequences over $X$ is well quasi ordered by the sequence embedding defined by $\sigma \leq_* \sigma'$ if and only if $\sigma = x_1 \cdots x_k$ and $\sigma' = \sigma'_0 x'_1 \sigma'_1 \cdots \sigma'_{k-1} x'_k \sigma'_k$ for some $x_j \leq_X x'_j$ in $X$ for $1 \leq j \leq k$ and some $\sigma'_j$ in $X^*$ for $0 \leq j \leq k$. For instance, finite sequences in $\Sigma^*$ for a finite alphabet $(\Sigma, =)$ form a wqo. This result is also known as **Higman’s Lemma.**

In the following, we call *elementary* those wqos obtained from finite sets $(X, =)$ through finitely many applications of Dickson’s and Higman’s lemmas. Note that $(\mathbb{N}, \leq)$ is elementary since it is isomorphic with finite sequences over some unary alphabet with equality.

4. **WQO Ideals**

Downward-closed sets $D$ can be denoted by a finite set of elements in $X$: since $X \setminus D$ is upward closed, it is the upward closure of a finite set $B \subseteq X \setminus D$ thanks to **Fact 3.4**. We deduce the following decomposition:

$$D = \bigcap_{x \in B} \left( X \setminus \uparrow x \right).$$
In this section, we recall an alternative way of decomposing downward-closed sets, namely as finite unions of ideals. This is a classical notion—Fraïssé [14, Section 4.5] attributes finite ideal decompositions to Bonnet [5]—which has been rediscovered in the study of well structured transition systems [13]. Let us review the basic theory of ideals, as can be found in [5, 14, 22, 13]; see in particular [16] for a gentle introduction.

4.1. Ideals. A subset $S$ of a qo $(X, \leq)$ is directed if for every $x_1, x_2 \in S$ there exists $x \in S$ such that both $x_1 \leq x$ and $x_2 \leq x$. An ideal $I$ is a directed non-empty downward-closed set. The class of ideals of $X$ is denoted by $\text{Idl}(X)$.\footnote{The set of ideals equipped with the inclusion relation is also called the completion of the wqo $(X, \leq)$, see [13].}

Example 4.1 (Well orders). In an ordinal $\alpha$ seen in set-theoretic terms as $\{\beta \mid \beta < \alpha\}$, any $\beta \leq \alpha$ is a downward-closed directed subset of $\alpha$, and conversely any downward-closed directed subset of $\alpha$ is some $\beta \leq \alpha$. Hence the ideals of $\alpha$ are exactly the elements of $\alpha + 1$ except 0. □

4.1.1. Ideals as Irreducible Downward-Closed Sets. An alternative characterisation of ideals shows that they are the irreducible downward-closed sets of a qo $(X, \leq)$:

Fact 4.2 (Ideals are Irreducible [22, 13, 16]). Let $I$ be a non-empty downward-closed set. The following are equivalent:

1. $I$ is an ideal,
2. for every pair of downward-closed sets $(D_1, D_2)$, if $I = D_1 \cup D_2$, then $I = D_1$ or $I = D_2$, and
3. for every pair of downward-closed sets $(D_1, D_2)$, if $I \subseteq D_1 \cup D_2$, then $I \subseteq D_1$ or $I \subseteq D_2$.

Because we find the proof of this fact in [22, 13, 16] enlightening, we recall the main ideas here:

Proof of $1 \Rightarrow 2$. Assume that $I$ is an ideal and let $(D_1, D_2)$ be two downward-closed sets such that $I = D_1 \cup D_2$. If $I = D_1$ we are done, so we can assume that there exists $x \in I \setminus D_1$. Because $D_2 \subseteq I$, it remains to prove that $I \subseteq D_2$.

Consider any $y \in I$. Because $I$ is directed, there exists $m \in I$ such that $x, y \leq m$. Observe that $m \in I \subseteq D_1 \cup D_2$ but $m \notin D_1$ since $D_1$ is downward-closed, $x \leq m$ and $x \notin D_1$. Thus $m \in D_2$, and since $D_2$ is downward-closed, $y \in D_2$. We have shown that $I \subseteq D_2$. □

Proof of $2 \Rightarrow 3$. Let $I$ be a non-empty downward-closed set satisfying item 2 and let $(D_1, D_2)$ be a pair of downward-closed sets with $I \subseteq D_1 \cup D_2$. Define $D_1' \overset{\text{def}}{=} D_1 \cap I$ and $D_2' \overset{\text{def}}{=} D_2 \cap I$: then $I = D_1'$ or $I = D_2'$ by item 2 and therefore $I \subseteq D_1'$ or $I \subseteq D_2'$. □

Proof of $3 \Rightarrow 1$. Let $I$ be a non-empty downward-closed set satisfying item 3. Consider $x_1, x_2 \in I$ along with the downward-closed sets $D_1 \overset{\text{def}}{=} X \setminus \uparrow x_1$ and $D_2 \overset{\text{def}}{=} X \setminus \uparrow x_2$. Observe that, if $I \subseteq D_1 \cup D_2$, by item 3 $I \subseteq D_1$ or $I \subseteq D_2$, and in both cases we get a contradiction with $x_1, x_2 \in I$. Hence,
there exists \( m \in I \setminus (D_1 \cup D_2) \), thus \( x_1, x_2 \leq m \) and we have shown that \( I \) is directed.

**Example 4.3 (Finite sets).** In a finite wqo \((X, \sqsubseteq)\), any subset of \( X \) is downward-closed. The ideals are thus exactly the singletons over \( X \): any other non-empty subset of \( X \) can be split into simpler sets.

**Corollary 4.4.** An ideal \( I \) is included in a finite union \( D_1 \cup \cdots \cup D_k \) of downward-closed sets \( D_1, \ldots, D_k \) if and only if \( I \subseteq D_j \) for some \( 1 \leq j \leq k \).

**Proof.** By induction on \( k \) using **Fact 4.2**.

4.1.2. **Finite Decompositions.** Observe that any downward-closed set of the form \( \downarrow x \) is an ideal, hence any downward-closed set is a union of ideals. However, the main interest we find with ideals is that they provide finite decompositions for downward-closed subsets of wqos:

**Fact 4.5 (Canonical Ideal Decompositions [22, 13, 16]).** Every downward-closed set over a wqo is the union of a unique finite family of incomparable (for the inclusion) ideals.

Let us again recall the proof as found in [22, 13, 16]:

**Proof.** Assume for the sake of contradiction that there exists a downward-closed set \( D \) of a wqo \((X, \leq)\), for which only infinite ideal decompositions exist. Because \((X, \leq)\) is a wqo, by **Fact 3.3** (Idl\((X, \subseteq)\) is well-founded and we can choose \( D \) minimal for inclusion. Observe that \( D \) is nonempty (or it would be an empty union of ideals). Whenever \( D = D_1 \cup D_2 \) for some downward-closed sets \( D_1 \) and \( D_2 \), there is \( i \in \{1, 2\} \) such that \( D_i \) requires an infinite ideal decomposition, and thus by minimality of \( D \), \( D = D_1 \). By **Fact 4.2** \( D \) is an ideal, contradiction. Finally, the unicity of the decomposition follows from **Corollary 4.4**.

The statement of **Fact 4.5** can be strengthened: it already holds for FAC partially ordered sets [see 5, 14, 22].

4.2. **Adherent Ideals.** Consider some subset \( S \) of \( X \). We call an ideal \( I \) of \( X \) an adherent ideal of \( S \), and say that \( I \) is in the adherence of \( S \), if there exists a directed subset \( \Delta \subseteq S \) such that \( \downarrow \Delta = I \).

By **Fact 4.5** the downward-closure \( \downarrow S \) has a canonical ideal decomposition. The following lemma shows that the ideals in this decomposition are in the adherence of \( S \).

**Lemma 4.6.** Let \((X, \leq)\) be a wqo and \( S \subseteq X \). Then every maximal ideal of \( \downarrow S \) is in the adherence of \( S \).

**Proof.** Assume that \( S \) is non-empty—or the lemma holds trivially. Let us write \( \downarrow S = J \cup J_1 \cup \cdots \cup J_k \) for the canonical decomposition of \( \downarrow S \). By minimality of this decomposition, there exists \( x_J \) in \( J \) such that \( x_J \not\in J_j \) for all \( 1 \leq j \leq k \). Thus any element \( s \) in \( \uparrow x_J \cap S \) must belong to \( J \).

Let us show that \( J \cap S \) is directed: for \( s, s' \in J \cap S \), because \( J \) is directed we first find \( y \) in \( J \) larger or equal to \( s, s' \), and \( x_J \). Since \( J \subseteq \downarrow S \), we then find \( s'' \geq y \) in \( S \). By the remark made in the previous paragraph, since \( s'' \geq x_J \), \( s'' \) also belongs to \( J \).
It remains to show that $J = \downarrow (J \cap S)$. It suffices to show the inclusion $J \subseteq \downarrow (J \cap S)$ since the converse inclusion is immediate. Consider any $y$ from $J$. Then there exists $y'$ in $J$ larger or equal to both $y$ and $x_J$, and again since $J \subseteq \downarrow S$ and by definition of $x_J$ there exists $s \geq y'$ in $J \cap S$. \qed

Later in Section 5 we will exploit Lemma 4.6 in a particular setting, where a downward-closed over-approximation $D$ of $S$ is known.

**Lemma 4.7.** Let $(X, \leq)$ be a wqo, $S \subseteq D \subseteq X$ for $D$ downward-closed, and $I$ be a maximal ideal of $D$. Then $I \subseteq \downarrow S$ if and only if $I$ is in the adherence of $S$.

**Proof.** If there exists a directed set $\Delta \subseteq S$ such that $I = \downarrow \Delta$, then $I \subseteq \downarrow S$.

Conversely, assume that $I \subseteq \downarrow S$. Because $I$ is non-empty, this means that $\downarrow S$ has a non-empty ideal decomposition into maximal ideals by Fact 4.5. Furthermore, by Corollary 4.4, $I$ is included into one of those maximal ideals $J$ of $\downarrow S$.

Because $J \subseteq D$, by Corollary 4.4 again there exists $I'$ a maximal ideal of $D$ with $J \subseteq I'$. Hence $I = J = I'$, or $I$ would not be a maximal ideal of $D$. Then Lemma 4.6 allows to conclude that $I = J$ is in the adherence of $S$. \qed

4.3. Effective Ideal Representations. Thanks to Fact 4.5, any downward-closed set has a representation using finitely many ideals. Should we manage to find effective representations of wqo ideals, this will provide us with algorithmic means to manipulate downward-closed sets. This endeavour is the subject of [13, 16], and we merely provide pointers to their results here.

4.3.1. Natural Numbers. As seen in Example 4.1, the ideals of $(\mathbb{N}, \leq)$ are either $\downarrow n$ for some finite $n \in \mathbb{N}$, or the whole of $\mathbb{N}$ itself. As done classically in the VAS literature, we represent the latter using a new element noted "$\omega$" with $n < \omega$ for all $n \in \mathbb{N}$, and denote the new set $\mathbb{N}_\omega \overset{\text{def}}{=} \mathbb{N} \cup \{\omega\}$. For notational convenience, we write $\downarrow \omega$ for $\mathbb{N}$, so that an ideal of $(\mathbb{N}, \leq)$ can be written as $\downarrow x$ for $x \in \mathbb{N}_\omega$.

4.3.2. Cartesian Products. Let $(X, \leq_X)$ and $(Y, \leq_Y)$ be two wqos, and assume that we know how to represent the ideals in $\text{Idl}(X)$ and $\text{Idl}(Y)$. Then the ideals of $X \times Y$ equipped with the product ordering have a simple enough representation as pairs of ideals:

$$\text{Idl}(X \times Y) = \{I \times J \mid I \in \text{Idl}(X) \land J \in \text{Idl}(Y)\}.$$  \hspace{1cm} (2)

Configurations. For example, configuration ideals can be represented as $\downarrow v$ for a vector $v$ in $\mathbb{N}_\omega^d$.

In this paper we often find it convenient to identify partial vectors $u$ in $\mathbb{N}^F$ for some subset $F \subseteq \{1, \ldots, d\}$ with vectors $v$ in $\mathbb{N}_\omega^d$ with finite values over $F$, such that $v(i) = \omega$ if $i \notin F$ and $v(i) = u(i)$ otherwise. Then projections $\pi_F: \mathbb{N}_\omega^d \to \mathbb{N}_\omega$ on a set $F \subseteq \{1, \ldots, d\}$ can be defined for all $1 \leq i \leq d$ by

$$\pi_F(u)(i) \overset{\text{def}}{=} \begin{cases} u(i) & \text{if } i \in F \\ \omega & \text{otherwise.} \end{cases} \hspace{1cm} (3)$$
Transitions. By Dickson’s Lemma, the product ordering over \( \mathbb{N}^d \times A \times \mathbb{N}^d \) is a wqo.

A **transition ideal** is an ideal of \( \mathbb{N}^d \times A \times \mathbb{N}^d \) that is the downward closure of a set of transitions of \( \text{Trans}_A \). As seen in Example 4.3, the ideals of \( A \) are the singletons \( \{a\} \) for \( a \in A \). By \cite{2}, the ideals of \( \mathbb{N}^d \times A \times \mathbb{N}^d \) can thus be presented as downward-closures of triples \((u, a, v)\) in \( \mathbb{N}^d \times A \times \mathbb{N}^d \).

Transition ideals are going to form a particular class of such triples. Let us define addition over \( \mathbb{Z} \cup \{\omega\} \) by \( k + \omega = \omega + k = \omega + \omega = \omega \). A **partial transition** is a triple \((u, a, v)\) in \( \mathbb{N}^d \times A \times \mathbb{N}^d \) such that \( v = u + a \). The following is immediate by continuity, but can also be given a non-topological proof:

**Lemma 4.8.** The transitions ideals of \( \mathbb{N}^d \times A \times \mathbb{N}^d \) are exactly the sets \( \downarrow t \) with \( t \) a partial transition.

**Proof.** First notice that \( \downarrow(u, a, u + a) \) for some \( u \) in \( \mathbb{N}^d \) and \( a \) in \( A \) is a transition ideal of \( \mathbb{N}^d \times A \times \mathbb{N}^d \); it is non-empty, directed, and the downward closure of a set of transitions in \( \text{Trans}_A \).

Conversely, let \( I \subseteq \text{Trans}_A \) be a transition ideal. There exists a set \( T \subseteq \text{Trans}_A \) such that \( I = \downarrow T \). Then \( I = \downarrow(u, a, v) \) for \( u, v \) in \( \mathbb{N}^d \) and \( a \) in \( A \). Let us show that \( v = u + a \). Assume for the sake of contradiction that there exists \( 1 \leq i \leq d \) such that \( v(i) < u(i) + a(i) \). There exists \( u' \) in \( \downarrow u \) such that \( v(i) < u'(i) + a(i) \). Moreover, since \( u' \) is in \( \downarrow u \), there exists \((u'', a, u'' + a)\) in \( T \) such that \( u' \leq u'' \). But then \( u'' + a \) does not belong to \( \downarrow v \) since \( u'' + a + a(i) \geq u'(i) + a(i) > v(i) \). This is a contradiction. The case where there exists \( 1 \leq i \leq d \) such that \( v(i) > u(i) + a(i) \) is similar. \( \square \)

Partial transitions can also be viewed as projected transitions:

\[
\pi_F((u, a, v)) \overset{\text{def}}{=} (\pi_F(u), a, \pi_F(v)).
\]  

(4)

4.3.3. **Finite Sequences.** In the case of sequences over a finite alphabet \((\Sigma, -)\), Jullien \cite{21} first characterised the ideals using a simple form of regular expressions, which was later rediscovered by Abdulla et al. \cite{1} for the verification of lossy channel systems. A representation of ideals for sequences over an arbitrary wqo \((X, \leq)\) was given by Kabil and Pouzet \cite{22} and also rediscovered in the context of well-structured systems by Finkel and Goubault-Larrecq \cite{13}.

Assume as before that we know how to represent the ideals in \( \text{Idl}(X) \). Define an **atom** \( A \) over \( X \) as a language \( A \subseteq X^* \) of the form \( A = D^* \) where \( D \) is a downward-closed set of \( X \)—i.e. a finite union of ideals from \( \text{Idl}(X) \)—, or form \( A = I \cup \{\varepsilon\} \) where \( I \) is an ideal from \( \text{Idl}(X) \) and \( \varepsilon \) denotes the empty sequence. A **product** \( P \subseteq X^* \) over \( X \) is a finite concatenation \( P = A_1 \cdots A_k \) of atoms \( A_1, \ldots, A_k \) over \( X \). We denote by \( \text{Prod}(X) \) the set of products over \( X \).

**Fact 4.9.** The ideals of \( X^* \) are the products over \( X \).

It is convenient for algorithmic tasks to have a canonical representation of ideals. In the case of products over \( X \), there is no uniqueness of representation, e.g. \((a + b)^* \cdot b^* \) denotes the same ideal as \((a + b)^* \) over \( X = \{a, b\} \). We can avoid such redundancies by considering **reduced** products \( P = A_1 \cdots A_k \), where for every \( j \), the following conditions hold:
(1) $A_j \neq \emptyset^*$,
(2) if $j + 1 \leq k$ and $A_{j+1}$ is some $D^*$, then $A_j \nsubseteq A_{j+1}$,
(3) if $j - 1 \geq 1$ and $A_{j-1}$ is some $D^*$, then $A_j \nsubseteq A_{j-1}$.

Because inclusion tests between effective representations of ideals are usually decidable, these conditions can effectively be enforced.

**Fact 4.10.** Every ideal of $X^*$ admits a canonical representation as a reduced product over $X$.

4.3.4. **Effectiveness.** In order to be usable in algorithms, wqo ideals need to be effectively represented. Following Goubault-Larrecq et al. [10], one can check that all the elementary wqos $(X, \leq)$ enjoy a number of effectiveness properties. Besides some basic desiderata, among which being able to decide whether (the representation of) two elements of $X$ coincide or are related through $\leq$, and similarly for $\text{Idl}(X)$ and the inclusion ordering, our elementary wqos are in particular equipped with (see [10] for details):

- **II**: an algorithm taking any pair of (representations of) ideals $I$ and $J$ in $\text{Idl}(X)$ and returning (a representation of) an ideal decomposition of $I \cap J$, and
- **CU**: an algorithm taking any (representation of an) element $x$ in $X$ and returning (a representation of) an ideal decomposition of $X \uparrow x$.

By combining those two algorithms, we get:

**Corollary 4.11 ([10]).** Let $(X, \leq)$ be an elementary wqo. There is an algorithm taking any (representation of an) ideal $I$ in $\text{Idl}(X)$ and any (representation of an) element $x$ in $X$ and returning (a representation of) an ideal decomposition of $I \uparrow x$.

5. A WQO on Runs

The key idea in our explanation of the KLMST decomposition is to see it as building the ideals of the downward-closure of $\text{Runs}_A(x, y)$ for an appropriate well quasi ordering defined by Jančar [20] and Leroux [30]. The reachability problem can then be restated as asking whether $\downarrow \text{Runs}_A(x, y)$ is non empty, i.e. whether the ideal decomposition of $\downarrow \text{Runs}_A(x, y)$ is empty or not.

5.1. Ordering PreRuns and Runs. There is a natural ordering $\leq$ of pre-runs. The product ordering over $\mathbb{N}^d \times A \times \mathbb{N}^d$ can be lifted to an embedding between sequences of tuples in $(\mathbb{N}^d \times A \times \mathbb{N}^d)^*$. Finally, we denote by $\leq$ the natural ordering over PreRuns$_A$ (see Figure 2 for an illustration in the particular case of runs). For a set of runs $\Omega$, we write $\downarrow \Omega$ for its downward-closure inside PreRuns$_A$, i.e.

$$\downarrow \Omega \equiv \{ \rho' \in \text{PreRuns}_A | \exists \rho \in \Omega. \rho' \leq \rho \} .$$ (5)

5.1.1. Transformer Relations. Embeddings between runs can also be understood in terms of transformer relations (aka production relations) à la Hauschildt [18] and Leroux [30, 31]: the relation $\searrow^c$ with capacity $c$ in $\mathbb{N}^d$ is the relation included in $\mathbb{N}^d \times \mathbb{N}^d$ defined by $u \searrow^c v$ if there exists a run from $u + c$ to $v + c$. 
5.1.2. Run Amalgamation. Leroux [30] observed that, thanks to monotonicity, each \(\prec\) is a periodic relation (see Section 2): \(0 \prec 0\), as witnessed by the empty run, and if \(u \prec v\) and \(u' \prec v'\), as witnessed by \(u + c \rightarrow v + c\) and \(u' + c \rightarrow v' + c\) respectively, then \(u + u' \prec v + v'\) as witnessed by \(u + u' + c \rightarrow v + v' + c\). Translated in terms of embeddings, the same reasoning shows:

**Proposition 5.1.** Let \(\rho_0, \rho_1,\) and \(\rho_2\) be runs with \(\rho_0 \leq \rho_1, \rho_2\). Then there exists a run \(\rho_3\) such that \(\rho_1, \rho_2 \leq \rho_3\).

**Proof.** Let \(\rho_0 = c_0 \overset{a_1}{\rightarrow} c_1 \cdots c_{k-1} \overset{a_k}{\rightarrow} c_k\). From \(\rho_0 \leq \rho_1\), we can write \(\rho_1 = v_0 + c_0 \overset{a_0}{\rightarrow} v_1 + c_0 \overset{a_1}{\rightarrow} v_1 + c_1 \cdots v_k + c_{k-1} \overset{a_k}{\rightarrow} v_k + c_k \overset{a_k}{\rightarrow} v_{k+1} + c_k\) where \(v_0, \ldots, v_{k+1}\) is a sequence of vectors in \(\mathbb{N}_d\). Symetrically, from \(\rho_0 \leq \rho_2\), we can write \(\rho_2 = v_0' + c_0' \overset{a_0}{\rightarrow} v_1' + c_0' \overset{a_1}{\rightarrow} v_1' + c_1 \cdots v_k' + c_{k-1} \overset{a_k}{\rightarrow} v_k' + c_k \overset{a_k}{\rightarrow} v_{k+1} + c_k\) where \(v_0', \ldots, v_{k+1}'\) is a sequence of vectors in \(\mathbb{N}_d\).

Define \(\rho_3 = v_0 + v_0' + c_0 \overset{a_0}{\rightarrow} v_1 + v_0' + c_0 \overset{a_0}{\rightarrow} v_1 + v_1' + c_0 \overset{a_1}{\rightarrow} v_1 + v_1' + \cdots v_k + v_k' + c_{k-1} \overset{a_k}{\rightarrow} v_k + v_k' + c_k \overset{a_k}{\rightarrow} v_{k+1} + v_k' + c_k \overset{a_k}{\rightarrow} v_{k+1} + v_{k+1}' + c_k\). \(\square\)

Note that the proof of Proposition 5.1 further shows that when \(\rho_0, \rho_1, \rho_2 \in \text{Runs}_A(x, y)\), then \(\rho_3 \in \text{Runs}_A(x, y)\) as well.

5.1.3. Prerun Ideals. By [Fact 4.9] and [Equation 2], the ideals of \(\text{PreRuns}_A\) are of the form \(\downarrow u \times P \times \downarrow v\) where \(u\) and \(v\) are in \(\mathbb{N}_d\) and \(P\) is a product over \(\mathbb{N}_d \times A \times \mathbb{N}_d\), i.e. can be represented as a regular expression over the alphabet \(\mathbb{N}_d \times A \times \mathbb{N}_d\).

5.2. Abstraction Refinement Procedure. Because runs are particular preruns, we can look at the downward-closure of \(\text{Runs}_A(x, y)\) inside \(\text{PreRuns}_A\).

By [Fact 4.5] this set has a finite decomposition using prerun ideals from \(\text{Idl(PreRuns}_A)\). This suggests an abstraction refinement procedure to compute the ideal decomposition of \(\downarrow \text{Runs}_A(x, y)\).

5.2.1. A Procedure for Reachability. An idea that looks promising is to build a descending sequence of downward-closed sets \(D_0 \supseteq D_1 \supseteq \cdots\) inside \(\text{PreRuns}_A\) while maintaining \(\downarrow \text{Runs}_A(x, y) \subseteq D_n\) at all steps, until we find the ideal decomposition of \(\downarrow \text{Runs}_A(x, y)\). By [Fact 4.5] we can work with finite sets of incomparable ideals to represent the \(D_n\)’s.

We start therefore with

\[
D_0 \overset{\text{def}}{=} \text{PreRuns}_A .
\]
Assume we are provided with an oracle to decide whether an ideal $I$ from $D_n$ is included in $\updownarrow \text{Runs}_A(x, y)$ and extract a counter-example otherwise. If $I \subseteq \updownarrow \text{Runs}_A(x, y)$ for all the (finitely many) maximal ideals $I$ in $D_n$ we stop; otherwise we find a maximal ideal $I$ from the decomposition of $D_n$ s.t.

$$\exists w \in I \setminus \updownarrow \text{Runs}_A(x, y)$$

and thanks to Corollary 4.11 we construct an ideal decomposition of

$$D' \equiv I \uparrow w$$

and we can refine $D_n$ and construct the downward-closed set for the next iteration—which involves removing redundant ideals—by

$$D_{n+1} \equiv D' \cup (D_n \setminus I).$$

The procedure terminates by Fact 3.3 but depends on an oracle to perform (7).

### 5.2.2. Adherence Membership

Turning the previous abstraction refinement procedure into an algorithm hinges on the effective checking of $I \subseteq \updownarrow \text{Runs}_A(x, y)$ for a maximal prerun ideal $I$ of $D_n$.

Note that, in general, deciding whether $I \subseteq \downarrow \text{Runs}_A(x, y)$ for a prerun ideal $I$ is at least as hard as VAS Reachability: observe indeed that $\downarrow(0, \varepsilon, 0) \subseteq \downarrow \text{Runs}_A(x, y)$ if and only if $\text{Runs}_A(x, y) \neq \emptyset$. We know this containment check to be decidable thanks to the Decomposition Theorem, but have at the moment no clue how to prove decidability without first assuming that there is an algorithm computing the ideal decomposition of $\text{Runs}_A(x, y)$.

We are therefore going to consider an adherence membership test instead. Indeed, by Lemma 4.7 and because $\text{Runs}_A(x, y) \subseteq D_n$ for all $n$, we know that this containment check is equivalent to testing whether $I$ is in the adherence of $\text{Runs}_A(x, y)$.

**Problem:** Adherence Membership of Prerun Ideals.

**input:** A $d$-dimensional VAS $A$, two configurations $x$ and $y$ in $\mathbb{N}^d$, and an ideal $I$ in $\text{Idl}(\text{PreRuns}_A)$.

**question:** Is $I$ in the adherence of $\text{Runs}_A(x, y)$?

As we show in App. A this problem in its full generality is undecidable:

**Theorem 5.2.** The adherence membership of prerun ideals is already undecidable for ideals of the form $\downarrow x \times D^* \times \downarrow x$ for $D$ a downward-closed subset of $\text{Trans}_A$ and $x$ in $\mathbb{N}^d$.

All is not lost however: we ask with the adherence membership problem for more than really needed. In the decomposition algorithm, $I$ presents some further structure that can be exploited towards an algorithm. This motivates a deeper investigation of the properties of run ideals, which will be the object of the next sections.

### 6. Local Adherent Ideals

We start our investigation of the ideals of $\downarrow \text{Runs}_A(x, y)$ by looking at rather restricted classes of runs. The treatment of this restricted case will
Figure 3. The set of runs $\Omega_\gamma$ in Example 6.1

turn out to contain most of the technical challenges of the next section on general run ideals, where we will assemble those local ideals into global ones.

More precisely, we focus on sets $\Omega_\gamma$ of runs of the form

$$c + u \overset{\sigma}{\rightarrow} c + v$$  \hspace{1cm} (10)

where $c$ is a configuration in $\mathbb{N}^d$, $\sigma$ is a sequence in $A^*$, and $(u, v)$ is a pair of configurations in a periodic set (see Section 2) $P$ included in the transformer relation $\overset{c}{\rightarrow}$. We write $\gamma$ for the pair $(c, P)$. As we are going to see in Lemma 6.3, $\downarrow \Omega_\gamma$ is an ideal of a particular form, for which an effective representation can be found, see Section 6.2.

6.1. Periodic Transformer Subrelations. Formally, let $\gamma$ denote a pair $(c, P)$ where $c$ is in $\mathbb{N}^d$ and $P \subseteq c \overset{c}{\rightarrow}$ is periodic. This is a familiar object, and we will reuse several statements from the literature. Following the notations from [31], let

- $\Omega_\gamma$ denote the set of runs of the form (10),
- $Q_\gamma \subseteq \mathbb{N}^d$ denote the set of configurations $q$ that appear along some run in $\Omega_\gamma$, thus in particular $c + u$ and $c + v$ belong to $Q_\gamma$ whenever $(u, v)$ are in $P$.

**Example 6.1.** Let us consider the 3-dimensional VAS $A = \{a, b\}$ where $a = (1, 1, -1)$ and $b = (-1, 0, 1)$, and the pair $\gamma = (c, P)$ where $c = (1, 0, 1)$ and $P = \mathbb{N}(0, y)$ with $y = (0, 1, 0)$. Note that $P$ is included in $c \overset{c}{\rightarrow}$ since there exists a run $c \overset{(ab)^n}{\rightarrow} c + ny$ for every $n$. We have

$$\Omega_\gamma = \{c \overset{w_1 \cdots w_n}{\rightarrow} c + ny \mid n \in \mathbb{N}, w_j \in \{ab, ba\}\} ,$$

$$Q_\gamma = (c + a + Ny) \cup (c + Ny) \cup (c + b + Ny) .$$

The set $\Omega_\gamma$ is depicted in Figure 3.

6.1.1. Saturated Pairs. We denote by $F_{\text{in}}^\gamma$ (resp. $F_{\text{out}}^\gamma$) the sets of indices $i$ such that $u(i) = 0$ (resp. $v(i) = 0$) for every pair $(u, v) \in P$. We say that a pair $(u, v)$ in $P$ saturates $(F_{\text{in}}^\gamma, F_{\text{out}}^\gamma)$ if $u(i) = 0$ implies $i \in F_{\text{in}}^\gamma$ and $v(i) = 0$ implies $i \in F_{\text{out}}^\gamma$. Since $P$ is periodic, by summing at most $2d$ pairs in $P$, we see that there exist pairs in $P$ that saturate $(F_{\text{in}}^\gamma, F_{\text{out}}^\gamma)$. 

We denote by \( \gamma \) some run in \( \Omega \) the set of partial transitions \( \pi \gamma \) by projecting the runs in \( \Omega \) with projection function \( \pi \). Note that this entails \( F \{ \) that

\[
\text{Projected Graphs.}
\]

6.2.2. Representation through Marked Witness Graphs. We investigate in this section how to effectively represent \( \downarrow \Omega \). In the sequel, we show that this ideal can be represented using the set of edges of a strongly connected graph called a witness graph (see [Lemma 6.2]) enjoying some pumping properties with respect to \( s^\text{in} \gamma \) and \( s^\text{out} \gamma \) (see [Lemma 6.4]). Such graphs will turn out to be exactly the ones employed by Lambert [26] in his variant of the KLMST decomposition (see also [29]).

6.2.1. Marked Witness Graphs. A witness graph is a strongly connected directed graph \( G = (S, E, s) \) where \( S \) is a non-empty finite set of partial configurations in \( \mathbb{N}^F \) for some \( F \subseteq \{1, \ldots, d\} \), \( E \subseteq S \times A \times S \) is a finite set of partially defined transitions, and \( s \) is a distinguished state in \( S \).

A marked witness graph is a triple \( M = (s^\text{in}, G, s^\text{out}) \) where \( G \) is a witness graph, and \( s^\text{in} \) and \( s^\text{out} \) are partial configurations in \( \mathbb{N}^F \) and \( \mathbb{N}^F \) for some \( F^\text{in}, F^\text{out} \supseteq F \) such that \( \pi_F(s^\text{in}) = \pi_F(s^\text{out}) = s \). We associate with \( M \) the set \( \Omega_M \) of runs \( \rho \) of the form \( x \xrightarrow{\sigma} y \) where \( \sigma \) is the label of a cycle on \( s \) in \( G \), and such that \( s^\text{in} = \pi_{F^\text{in}}(x) \) and \( s^\text{out} = \pi_{F^\text{out}}(y) \).

6.2.2. Projected Graphs. Let \( F_\gamma \subseteq \{1, \ldots, d\} \) denote the set of indices \( i \) such that \( \{q(i) \mid q \in Q_\gamma\} \) is finite, i.e. the indices where \( Q_\gamma \) remains bounded. Note that this entails \( F_\gamma \subseteq F^\text{in}_\gamma \) and \( F_\gamma \subseteq F^\text{out}_\gamma \). We denote by \( \pi_\gamma \) the projection function \( \pi_{F_\gamma} \).

Observe that the projection \( S_\gamma = \pi_\gamma(Q_\gamma) \) of \( Q_\gamma \) is finite, and so is \( E_\gamma \) the set of partial transitions \( \{\pi_\gamma(q), a, \pi_\gamma(q')\} \) where \( (q, a, q') \) appears in some run in \( \Omega_\gamma \). We distinguish \( s_\gamma = \pi_\gamma(c) \) as a particular state in \( S_\gamma \). We denote by \( G_\gamma = (S_\gamma, E_\gamma, s_\gamma) \) the finite labelled directed graph defined by projecting the runs in \( \Omega_\gamma \), and \( M_\gamma = (s^\text{in}_\gamma, G_\gamma, s^\text{out}_\gamma) \) the corresponding marked graph with input \( s^\text{in}_\gamma \) and output \( s^\text{out}_\gamma \).

\[
\text{Example 6.1 (continued). We have for our example:}
\]

\[
F^\text{in}_\gamma = \{1, 2, 3\}, \quad F^\text{out}_\gamma = \{1, 3\}, \quad s^\text{in}_\gamma = (1, 0, 1), \quad s^\text{out}_\gamma = (1, \omega, 1).
\]

Note that \((0, y)\) saturates \((F^\text{in}_\gamma, F^\text{out}_\gamma)\). \(\Box\)
Example 6.1 (continued). Projecting $Q_{\gamma}$ on $F_{\gamma} = \{1, 3\}$ yields $\pi_{\gamma}(c + a + ny) = (2, \omega, 0)$, $\pi_{\gamma}(c + ny) = (1, \omega, 1)$, and $\pi_{\gamma}(c + b + ny) = (0, \omega, 2)$:

\[ s_{\gamma} = (1, \omega, 1) , \quad S_{\gamma} = \{(2, \omega, 0), (1, \omega, 1), (0, \omega, 2)\}. \]

The graph $G_{\gamma}$ is depicted on Figure 4.

We associate to a prerun $\rho = (x, t_1 \cdots t_k, y)$ and a set $F \subseteq \{1, \ldots, d\}$, the partial prerun:

\[ \pi_F(\rho) \overset{\text{def}}{=} (\pi_F(x), \pi_F(t_1) \cdots \pi_F(t_k), \pi_F(y)) \]

If $\rho$ is a run in $\Omega_{\gamma}$, then $\pi_{\gamma}(\rho)$ is a path inside $G_{\gamma}$, and by [31, Corollary VIII.5], $\pi_{\gamma}(x) = \pi_{\gamma}(y) = s_{\gamma}$, which means that this path is actually a cycle in $G_{\gamma}$. This in turn shows that $G_{\gamma}$ is strongly connected. This proves:

**Lemma 6.2.** The marked graph $M_{\gamma}$ is a marked witness graph such that $\Omega_{\gamma} \subseteq \Omega_{M_{\gamma}}$.

6.2.3. Intraproductions. An intraproduction for $\gamma$ is a vector $h$ in $\mathbb{N}^d$ such that $c + h$ belongs to $Q_{\gamma}$. We denote by $H_{\gamma}$ the set of intraproductions for $\gamma$; note that it contains in particular $u$ and $v$ if $(u, v) \in P$.

Leroux [31, Lemma VIII.3] shows that $H_{\gamma}$ is periodic and $Q_{\gamma} + H_{\gamma} \subseteq Q_{\gamma}$. Following the proof of that lemma, denoting by $T_{\gamma}$ the set of transitions occurring along runs of $\Omega_{\gamma}$, we deduce that if $t = (p, a, q)$ is in $T_{\gamma}$, and $h$ in $H_{\gamma}$ is an intraproduction, then the transition $t + h \overset{\text{def}}{=} (p + h, a, q + h)$ also occurs in some run of $\Omega_{\gamma}$, i.e. $t + h \in T_{\gamma}$. It follows that, if $h$ in $H_{\gamma}$ is such that $h(i) > 0$ for some index $i$, then $i$ cannot belong to $F_{\gamma}$, since $c + nh$ is in $Q_{\gamma}$ for all $n$. This entails in particular that $h = 0$ if $F_{\gamma} = \{1, \ldots, d\}$.

A kind of converse property sometimes holds: we say that an intraproduction $h$ in $H_{\gamma}$ saturates $F_{\gamma}$ if whenever $h(i) = 0$, then $i$ belongs to $F_{\gamma}$, and therefore $F_{\gamma} = \{i \mid h(i) = 0\}$. Leroux [31, Lemma VIII.3] shows there exist intraproductions $h$ in $H_{\gamma}$ that saturate $F_{\gamma}$.

Example 6.1 (continued). To continue with our example, the set of intraproductions is $H_{\gamma} = \mathbb{N}y$. The only non-saturated intraproduction is $0$, as any $ny$ with $n > 0$ saturates $F_{\gamma}$.

By similarly shifting every word $w = t_1 \cdots t_k$ of transitions in $T_{\gamma}^*$ to the word $w + h \overset{\text{def}}{=} (t_1 + h) \cdots (t_k + h)$ where $h$ is an intraproduction that saturates $F_{\gamma}$, we can show the following characterisation of $\downarrow \Omega_{\gamma}$:

**Lemma 6.3.** The following equality holds:

\[ \downarrow \Omega_{\gamma} = \downarrow s_{\gamma}^{\text{in}} \times (\downarrow E_{\gamma})^* \times \downarrow s_{\gamma}^\text{out}. \]

Proof. The inclusion $\subseteq$ is immediate. For the converse inclusion, let us denote by $T_{\gamma}$ the set of transitions occurring along runs of $\Omega_{\gamma}$. Now, consider any word $w = t_1 \cdots t_k$ of transitions in $T_{\gamma}^*$, there exists an intraproduction $h$ that saturates $F_{\gamma}$ and a pair $(u_0, v_0)$ in $P$ that saturates $(F_{\gamma}^\text{in}, F_{\gamma}^\text{out})$. We denote by $w + h$ the word $(t_1 + h) \cdots (t_k + h)$. Since $t_j + h$ is a transition in $T_{\gamma}$, it occurs along some run $c + u_j \overset{\sigma_j}{\rightarrow} c + v_j$ of $\Omega_{\gamma}$. Moreover, as $(u_0, v_0)$ is in $P$, there exists a run $c + u_0 \overset{\sigma_0}{\rightarrow} c + v_0$. Let $u = \sum_{j=0}^k u_j$,
Let $\mathbf{v} \overset{\text{def}}{=} \sum_{j=0}^{k} \mathbf{v}_j$, and $\mathbf{\sigma} \overset{\text{def}}{=} \sigma_0 \cdots \sigma_k$. Because $\mathbf{P}$ is periodic, it follows that $(\mathbf{u}, \mathbf{v})$ is a pair in $\mathbf{P}$. Notice that $\rho \overset{\text{def}}{=} (\mathbf{c} + \mathbf{u} \xrightarrow{c} \mathbf{c} + \mathbf{v})$ is a run in $\Omega$, and $(\mathbf{c} + \mathbf{u}_0, \mathbf{w} + \mathbf{h}, \mathbf{c} + \mathbf{v}_0) \in \downarrow \rho$. Hence $\downarrow((s^\text{in}_\gamma, \pi_\gamma(w), s^\text{out}_\gamma)) \subseteq \downarrow \Omega_l$, proving the converse inclusion.

Leroux [31, Lemma VIII.11] shows that $S_\gamma$ is a set of incomparable partial configurations. Therefore the partial transitions in $E_\gamma$ are incomparable. The previous lemma then shows that $E_\gamma$ is the unique finite set of incomparable elements in $\mathbb{N}_+^d \times \mathbb{A} \times \mathbb{N}_+^d$ satisfying Lemma 6.3.

6.2.4. Pumpable Configurations. A partial configuration $\mathbf{x}$ in $\mathbb{N}_+^d$ is said to be forward pumpable by a witness graph $G = (S, E, \mathbf{s})$ if there exists a cycle on $\mathbf{s}$ labelled by a word $\sigma_+$, and a run using this label $\mathbf{x} \xrightarrow{\sigma_+} \mathbf{x}'$ with $\mathbf{x} \leq \mathbf{x}'$ such that $\downarrow \mathbf{s} = \bigcup_n \downarrow \mathbf{x}_n$, where $\mathbf{x}_n$ is the configuration defined by $\mathbf{x} \xrightarrow{\sigma_+^n} \mathbf{x}_n$ (such a configuration exists by monotonicity). Symmetrically, a partial configuration $\mathbf{y}$ in $\mathbb{N}_+^d$ is said to be backward pumpable by a witness graph $G = (S, E, \mathbf{s})$ if there exists a cycle on $\mathbf{s}$ labelled by a word $\sigma_-$, and a run $\mathbf{y}' \xrightarrow{\sigma_-^n} \mathbf{y}$ with $\mathbf{y} \leq \mathbf{y}'$ such that $\downarrow \mathbf{s} = \bigcup_n \downarrow \mathbf{y}_n$ where $\mathbf{y}_n$ is the configuration defined by $\mathbf{y} \xrightarrow{\sigma_-^n} \mathbf{y}_n$.

Saturated intraproductions also provide a way to prove that the graph input $s^\text{in}_\gamma$ and output $s^\text{out}_\gamma$ are pumpable.

**Lemma 6.4.** The input $s^\text{in}_\gamma$ is forward pumpable by $G_\gamma$, and the output $s^\text{out}_\gamma$ is backward pumpable by $G_\gamma$.

**Proof.** Let $\mathbf{h}$ be an intraproduction that saturates $F_\gamma$. There exists a run $\rho \overset{\text{def}}{=} \mathbf{c} + \mathbf{u}_h \xrightarrow{\sigma_+} \mathbf{c} + \mathbf{h} \xrightarrow{\sigma_-} \mathbf{c} + \mathbf{v}_h$ in $\Omega_l$. The projection $\pi_\gamma(\rho)$ shows that $\sigma_+, \sigma_-$ are cycles on $s_\gamma$. Moreover, by projecting over $F^\text{in}_\gamma$ the run $\mathbf{c} + \mathbf{u}_h \xrightarrow{\sigma_+} \mathbf{c} + \mathbf{h}$ we see that $s^\text{in}_\gamma \xrightarrow{\sigma_+} s^\text{in}_\gamma + h$. Hence $s^\text{in}_\gamma$ is forward pumpable by $G_\gamma$. Symmetrically $s^\text{out}_\gamma$ is backward pumpable by $G_\gamma$. □

7. **Global Adherent Ideals**

Our understanding of the KLMST decomposition is that it builds an ideal decomposition of $\downarrow \text{Runs}_A(\mathbf{x}, \mathbf{y})$ inside $\text{PreRuns}_A$. We have seen in Section 5.1 how to represent prerun ideals. However we should expect the maximal ideals of $\downarrow \text{Runs}_A(\mathbf{x}, \mathbf{y})$ to have additional properties besides adherence, and indeed we shall see they can be represented using the structures employed in the KLMST decomposition.

The starting point for our characterisation of run ideals is to consider some finite basis $B$ of $(\text{Runs}_A(\mathbf{x}, \mathbf{y}), \subseteq)$: if we consider the upward closure $\uparrow \rho \cap \text{Runs}_A(\mathbf{x}, \mathbf{y})$ of each run $\rho$ in $B$ inside $\text{Runs}_A(\mathbf{x}, \mathbf{y})$, we obtain again

$$\text{Runs}_A(\mathbf{x}, \mathbf{y}) = \bigcup_{\rho \in B} \uparrow \rho \cap \text{Runs}_A(\mathbf{x}, \mathbf{y}) \, .$$

(12)

Taking the downward-closure inside $\text{PreRuns}_A$ then yields

$$\downarrow \text{Runs}_A(\mathbf{x}, \mathbf{y}) = \bigcup_{\rho \in B} \downarrow (\uparrow \rho \cap \text{Runs}_A(\mathbf{x}, \mathbf{y})) \, ,$$

(13)
prompting the study of $\downarrow(\uparrow\rho \cap \text{Runs}_{\mathcal{A}}(x, y))$.

7.1. Maximal Ideals. Observe that each set $\downarrow(\uparrow\rho \cap \text{Runs}_{\mathcal{A}}(x, y))$ for a run $\rho$ is downward-closed and non-empty, and that by Proposition 5.1 it is also directed, and is therefore an ideal.

We can further see that those ideals are exactly the maximal ideals in the canonical decomposition of $\downarrow \text{Runs}_{\mathcal{A}}(x, y)$.

**Proposition 7.1.** The maximal ideals from the canonical decomposition of $\downarrow \text{Runs}_{\mathcal{A}}(x, y)$ are exactly the sets $\downarrow(\uparrow\rho \cap \text{Runs}_{\mathcal{A}}(x, y))$ for some runs $\rho$ in $\text{Runs}_{\mathcal{A}}(x, y)$.

**Proof.** For any run $\rho$, because $\downarrow(\uparrow\rho \cap \text{Runs}_{\mathcal{A}}(x, y))$ is an ideal, it is included into some maximal ideal $I$. By Lemma 4.6 $I = \downarrow \Delta$ for some directed subset $\Delta$ of $\text{Runs}_{\mathcal{A}}(x, y)$. Let us show that $I \subseteq \downarrow(\uparrow\rho \cap \Delta)$, which will show that $I \subseteq \downarrow(\uparrow\rho \cap \text{Runs}_{\mathcal{A}}(x, y))$ and thereby the maximality of $\downarrow(\uparrow\rho \cap \text{Runs}_{\mathcal{A}}(x, y))$.

Since $\rho$ is in $I$, there is a run $\rho_{\Delta}$ in $\Delta$ such that $\rho \leq \rho_{\Delta}$. Then, for any prerun $\rho_0$ in $I$, since $I$ is directed there exists $\rho_1$ in $I$ with $\rho_{\Delta}, \rho_0 \leq \rho_1$. Finally, since $I = \downarrow \Delta$, there exists $\rho_2$ in $\Delta$ such that $\rho_1 \leq \rho_2$, i.e. $\rho_2 \in \uparrow \rho \cap \Delta$ as desired.

Conversely, if $I$ is a maximal ideal of $\downarrow \text{Runs}_{\mathcal{A}}(x, y)$, then by Lemma 4.6 it is adherent and thus equal to $\downarrow \Delta$ for some directed subset $\Delta$ of runs in $\text{Runs}_{\mathcal{A}}(x, y)$. Pick some $\rho_0$ in $\Delta$; then $I \subseteq \downarrow(\uparrow\rho_0 \cap \text{Runs}_{\mathcal{A}}(x, y))$, and equality follows from the maximality of $I$.

Note that the sets $\downarrow(\uparrow\rho \cap \text{Runs}_{\mathcal{A}}(x, y))$ and $\downarrow(\uparrow\rho' \cap \text{Runs}_{\mathcal{A}}(x, y))$ for $\rho \neq \rho'$ might coincide, even for minimal $\rho$ and $\rho'$, so there is no canonicity in terms of those basic runs.

What we seek now is a more syntactic representation for such ideals, which would not require to explicitly exhibit a run $\rho$.

7.2. Perfect Runs. Let us accordingly fix a run $\rho = c_0 \xrightarrow{a_1} c_1 \cdots c_{k-1} \xrightarrow{a_k} c_k$ with $x = c_0$ and $y = c_k$ throughout this subsection.

7.2.1. Transformer Relations Along a Run. Consider the relation $R$ of tuples $((u_0, v_0), \ldots, (u_k, v_k))$ of pairs in $\mathbb{N}^d \times \mathbb{N}^d$ such that:

$$0 = u_0 \cap v_0 = u_1 \cap v_1 = \cdots = u_k \cap v_k = 0$$

and let us introduce the relation $P_j$ defined for $0 \leq j \leq k$ by:

$$P_j \overset{\text{def}}{=} \{(u_j, v_j) \mid ((u_0, v_0), \ldots, (u_k, v_k)) \in R\}.$$ (15)

Informally, each $P_j$ is the subset of $c_j$ that can be completed into some run in $\uparrow\rho \cap \text{Runs}_{\mathcal{A}}(x, y)$. We can check that $R$ and each $P_j$ is a periodic relation since each transformer relation is periodic.

7.2.2. Global Ideal Representation. Denoting by $\gamma_j$ the pair $(c_j, P_j)$, we derive from Lemma 6.3 the following equality:

$$\downarrow \Omega_{\gamma_j} = \downarrow s_{\gamma_j}^\text{in} \times (\downarrow E_{\gamma_j})^* \times \downarrow s_{\gamma_j}^\text{out}.$$ (16)

Notice that $s_{\gamma_0}^\text{in} = x$ and $s_{\gamma_k}^\text{out} = y$. Moreover, the triple $e_j \overset{\text{def}}{=} (s_{\gamma_{j-1}}^\text{out}, a_j, s_{\gamma_j}^\text{in})$ is a partial transition for every $1 \leq j \leq k$. 

Observe that $\downarrow(\uparrow \rho \cap \text{Runs}_A(x, y))$ is included in
\[ \downarrow x \times (\downarrow E_{y_0})^* \cdot A_0 \cdot (\downarrow E_{y_1})^* \cdot \ldots \cdot A_k \cdot (\downarrow E_{y_k})^* \times \downarrow y \] (17)
where $A_j$ is the atom $\downarrow e_j \cup \{\varepsilon\}$. The converse inclusion will be a consequence of Lemma 7.3 and Lemma 7.5.

In the upcoming subsection, we derive a condition satisfied by the following sequence $\xi_\rho$ of interspersed marked witness graphs and actions, which allows to represent the ideal (17):

\[ \xi_\rho \overset{\text{def}}{=} M_{0}, a_1, M_{1}, \ldots, a_k, M_k. \] (18)

### 7.3. Perfect Marked Witness Graph Sequences

A marked witness graph sequence $\xi$ is a sequence
\[ \xi = M_0, a_1, M_1, \ldots, a_k, M_k, \] (19)
where $M_0, \ldots, M_k$ are marked witness graphs and $a_1, \ldots, a_k$ are actions in $A$. In the sequel, $M_j$ denotes the marked witness graph $(s_j^{\text{in}}, G_j, s_j^{\text{out}})$ where $G_j$ is the witness graph $(S_j, E_j, s_j)$. The sets $F_j^{\text{in}}, F_j, F_j^{\text{out}}$ denote the finite coordinates of $s_j^{\text{in}}, s_j, s_j^{\text{out}}$. The two partial configurations $s_0^{\text{in}}$ and $s_k^{\text{out}}$ are assumed to be respectively $x$ and $y$. Such sequences $\xi$ are also called marked graph-transition sequences in [26], and are the structures maintained throughout the KLMST decomposition algorithm.

#### 7.3.1. Ideals and Runs

A marked witness graph sequence $\xi$ defines a prerun ideal
\[ I_\xi \overset{\text{def}}{=} \downarrow x \times (\downarrow E_0)^* \cdot A_1 \cdot (\downarrow E_1)^* \cdot \ldots \cdot A_k \cdot (\downarrow E_k)^* \times \downarrow y \] (20)
where $A_j \overset{\text{def}}{=} \downarrow (s_j^{\text{out}}, a_j, s_j^{\text{in}}) \cup \{\varepsilon\}$ for all $1 \leq j \leq k$. It is also associated with a set of runs $\Omega_\xi$ of the form
\[ x_0 \xrightarrow{\sigma_0} y_0 \xrightarrow{a_1} x_1 \xrightarrow{\sigma_1} y_1 \ldots \xrightarrow{a_k} x_k \xrightarrow{\sigma_k} y_k \] (21)
where each $x_j \xrightarrow{\sigma_j} y_j$ is a run in $\Omega_{M_j}$. Note that $\downarrow \Omega_\xi \subseteq I_\xi$.

We show next in Lemma 7.3 that for marked witness graph sequences $\xi$ which satisfy the perfectness condition of Lambert [26]—which is mostly equivalent to Kosaraju’s theta condition—, the prerun ideal $I_\xi$ associated with $\xi$ is adherent. This condition is not arbitrary, but stems from the properties of the sequences $\xi_\rho$ we derived in sections 6 and 7.

#### 7.3.2. Perfectness Condition

Perfectness is defined by introducing a linear system over the natural numbers that denotes a set $L_\xi$ of solutions. This linear system relies on a binary relation $\psi$ over configurations in $\mathbb{N}^d$, where $\psi: E \rightarrow \mathbb{N}$ denotes some function defined on a finite set $E$ of partial transitions. The relation is defined by $x \xrightarrow{\psi} y$ if $y = x + \sum_{e \in E} \psi(e) \Delta(e)$, where $\Delta(e) \overset{\text{def}}{=} a$ for a partial transition $e$ labelled by $a$.

Let $L_\xi$ be the set of tuples $(x_0, \psi_0, y_0, \ldots, x_k, \psi_k, y_k)$ where $\psi_j: E_j \rightarrow \mathbb{N}$ is a function satisfying for every $s \in S_j$:
\[ \sum_{e \in E_j | \sigma_j(e) = s} \psi_j(e) = \sum_{e \in E_j | \delta_j(e) = s} \psi_j(e) \]
and \( x_0, y_0, \ldots, x_k, y_k \) are configurations in \( \mathbb{N}^d \) such that
\[
\begin{align*}
x_0 &\xrightarrow{\psi_0} y_0 \\
x_0 &\xrightarrow{\psi_1} x_1 \\
&\ldots \\
x_0 &\xrightarrow{\psi_k} x_k \rightarrow y_k
\end{align*}
\]
and such that for every \( 0 \leq j \leq k \)
\[
\pi_{F_{j\text{in}}}(x_j) = s_j^{\text{in}} \land \pi_{F_{j\text{out}}}(y_j) = s_j^{\text{out}}.
\]
Notice that \( L_\xi \) is defined as solutions of a linear system. Moreover, for every run in \( \Omega_\xi \) of the form \( (21) \), by introducing the Parikh image \( \psi_j: E_j \rightarrow \mathbb{N} \) of the cycle on \( s_j \) labelled by \( \sigma_j \), we get a sequence \( ((x_0, \psi_0, x_1), \ldots, (x_k, \psi_k, y_k)) \) in \( L_\xi \).

**Definition 7.2.** A marked witness graph sequence is said to be perfect if it satisfies the following conditions for all \( j \):
- \( s_j^{\text{in}} \) and \( s_j^{\text{out}} \) are respectively forward and backward pumpable by \( G_j \),
- \( \sup X_j = s_j^{\text{in}} \) and \( \sup Y_j = s_j^{\text{out}} \),
- \( \sup \Psi_j(e) = \omega \) for every \( e \in E_j \), and

where \( X_j, \Psi_j, \) and \( Y_j \) are resp. the sets of elements \( x_j, \psi_j, \) and \( y_j \) satisfying:
\[
((x_0, \psi_0, y_0), \ldots, (x_k, \psi_k, y_k)) \in L_\xi.
\]

Perfect witness graph sequences denote adherent ideals:

**Lemma 7.3.** If \( \xi \) is a perfect marked witness graph sequence, then \( I_\xi \) is in the adherence of \( \text{Runs}_A(x, y) \) and \( I_\xi = \downarrow \Omega_\xi \).

**Proof.** The proof comes from \( [26, \text{Lemma 4.1}] \) and shows that a directed family of runs of the following form can always be extracted from a perfect marked witness graph sequence:
\[
\begin{align*}
x_{0,n} &\xrightarrow{\sigma^\circ_n a_0^n wo^n \sigma_0^n} y_{0,n} \\
x_{1,n} &\xrightarrow{a_1^n} x_{1,n} \\
&\ldots \\
x_{k,n} &\xrightarrow{\sigma_k^n w_k \sigma^n_k} y_{k,n}
\end{align*}
\]

such that each run family \( x_{j,n}, y_{j,n} \) is directed with \( \downarrow \Omega_{M_j} \) as downward-closure. Intuitively, \( \sigma_{\neg j} \) pumps up the components in \( F_{j\text{in}} \setminus F_j \), \( \sigma_{\neg j} \) pumps down those in \( F_{j\text{out}} \setminus F_j \), and \( \sigma_j \) is the label of a cycle on \( s_j \) such that every transition in \( E_j \) occurs at least once along the cycle. The sequence \( w_j \) comes from a solution of the linear system \( L_\xi \). \( \square \)

### 7.3.3. Deciding Perfectness

We can decide if a marked witness graph sequence is perfect as follows. First of all, observe that checking if a partial configuration \( x \in \mathbb{N}^d \) is pumpable (either backward or forward) by a witness graph \( G = (S, E, s) \) can be performed in exponential space since this problem reduces to the place boundedness problem for vector addition systems \( [2, 9] \). Moreover, since we can compute the unbounded components of the set of solutions of a linear system on \( \mathbb{N} \) in nondeterministic polynomial time, we can effectively do this computation on sets \( L_\xi \) of solutions for marked witness graph sequences \( \xi \). Hence:

**Lemma 7.4.** The perfectness of a marked witness graph sequence is decidable in exponential space.
7.4. Run Ideals. We have seen that the downward closed set $\downarrow \text{Runs}_A(x, y)$ can be decomposed as a finite union of ideals $I_\xi$, where $\xi$ is the marked witness graph sequence associated to $\rho$. By the following lemma, this implies that $\downarrow \text{Runs}_A(x, y)$ can be represented using a finite set of perfect marked witness graph sequences.

**Lemma 7.5.** The marked witness graph sequence $\xi_\rho$ is perfect for every run $\rho$.

**Proof.** By Lemma 6.4, for all $j$, $s_{\gamma_j}^i$ and s_{\gamma_j}^j$ are resp. forward and backward pumpable by $G_j$.

Regarding the conditions on $L_{\xi_\rho}$, for every tuple $((u_0, v_0), \ldots, (u_k, v_k))$ in $R$, every sequence family $(\sigma_j)_{1 \leq j \leq k}$ in $A^*$ such that $\rho_j \overset{\text{def}}{=} (c_j + u_j \sigma_j, c_j + v_j)$, and every $n \in \mathbb{N}$, we observe that

$$(c_0 + nu_0, nv_0, c_0 + nv_0), \ldots, (c_k + nu_k, nv_k, c_k + nv_k)$$

is in $L_{\xi_\rho}$ where $\psi_j: E_j \to \mathbb{N}$ is the Parikh image of the cycle $\pi_{\gamma_j}(\rho_j)$ on $s_j$ in $G_j$. In particular, if $s_{\gamma_j}^i(i) = \omega$ for some $i \in F_{\gamma_j}^i$, and some $0 \leq j \leq k$, then there exists $(u_j, v_j) \in P_j$ such that $u_j(i) > 0$. By completing this pair as a tuple $((u_0, v_0), \ldots, (u_k, v_k))$ in $R$, we deduce that $\sup X_j(i) = \omega$. Thus $\sup X_j = s_{\gamma_j}^i$ and we get similarly $\sup Y_j = s_{\gamma_j}^j$ and $\sup \Psi_j(e) = \omega$ for every $e \in E_j$. Thus $\xi_\rho$ is perfect.

**Theorem 7.6.** For any perfect marked witness graph sequence $\xi$, $I_\xi \subseteq \downarrow \text{Runs}_A(x, y)$. Moreover, there exists a finite set $\Xi$ of perfect marked witness graph sequences such that

$$\downarrow \text{Runs}_A(x, y) = \bigcup_{\xi \in \Xi} I_\xi.$$

8. The Decomposition Algorithm

We explain succinctly in this section how the classical KLMST algorithm of Mayr, Kosaraju, and Lambert computes the decomposition of $\downarrow \text{Runs}_A(x, y)$ into ideals. By Theorem 7.6 these ideals can be presented as finite families of perfect marked witness graph sequences.

The KLMST algorithm operates along the same general lines as the abstraction refinement procedure of Section 5.2. It refines successively a finite family $\Xi_n$ of marked witness graph sequences from $x$ to $y$ while maintaining as an invariant

$$\text{Runs}_A(x, y) = \bigcup_{\xi \in \Xi_n} \Omega_\xi$$

for all $n$. Because $\downarrow \Omega_\xi \subseteq I_\xi$ for all $\xi$, this implies

$$\downarrow \text{Runs}_A(x, y) \subseteq D_n \overset{\text{def}}{=} \bigcup_{\xi \in \Xi_n} I_\xi$$

as in the abstraction refinement procedure.

If every marked witness graph sequence in $\Xi_n$ is perfect (which is decidable by Lemma 7.4), the algorithm stops since by Lemma 7.3

$$\downarrow \text{Runs}_A(x, y) = \bigcup_{\xi \in \Xi_n} I_\xi.$$
Otherwise, the family $\Xi_n$ is decomposed into a new family $\Xi_{n+1}$ as follows: we pick a marked witness graph sequence $\xi \in \Xi_n$ that is not perfect. The imperfectness of $\xi$ provides a way of computing a new finite family $\text{dec}(\xi)$ of marked witness graph sequences from $x$ to $y$ (see Section 8.2) with

$$\Omega_\xi = \bigcup_{\xi' \in \text{dec}(\xi)} \Omega_{\xi'}.$$  \hfill (26)

The family $\Xi_{n+1}$ is then defined as

$$\Xi_{n+1} \overset{\text{def}}{=} (\Xi_n \setminus \{\xi\}) \cup \text{dec}(\xi).$$  \hfill (27)

Termination is ensured through a ranking function relating $\xi$ with each sequence in $\text{dec}(\xi)$, see Section 8.3. The KLMST algorithm shows:

**Theorem 8.1** (Decomposition Theorem). The ideal decomposition of $\downarrow \text{Runs}_A(x, y)$ inside $\text{PreRuns}_A$ is effectively computable.

Because $\downarrow \text{Runs}_A(x, y) = \emptyset$ if and only if $\text{Runs}_A(x, y) = \emptyset$, this yields:

**Theorem 8.2** (Mayr [34], Kosaraju [24], Lambert [26]). VAS reachability is decidable.

8.1. **Initial Family.** The KLMST algorithm starts with an initial family $\Xi_0$ containing a single marked witness graph sequence $\xi_0$, itself reduced to a single marked witness graph $M_0 \overset{\text{def}}{=} (x, G, y)$ where $G \overset{\text{def}}{=} (S, E, s)$ is defined by $s = (\omega, \ldots, \omega)$, $S = \{s\}$, and $E = S \times A \times S$. Note that $\Omega_{\xi_0} = \text{Runs}_A(x, y)$ and

$$\downarrow \text{Runs}_A(x, y) \subseteq D_0 = \downarrow x \times (\mathbb{N}^d \times A \times \mathbb{N}^d)^* \times \downarrow y.$$  \hfill (28)

8.2. **Decomposition.** Let us fix a marked witness graph sequence $\xi$ that is not perfect, and let us recall how the finite family $\text{dec}(\xi)$ is obtained in the KLMST algorithm. We assume that

$$\xi = M_0, a_1, M_1, \ldots, a_k, M_k,$$

where $M_0, \ldots, M_k$ are marked witness graphs, and $a_1, \ldots, a_k$ are actions in $A$. In the sequel, $M_j$ denotes the marked witness graph $(s_j^\text{in}, G_j, s_j^\text{out})$ and $G_j$ is the witness graph $(S_j, E_j, s_j)$. We let $F_j^\text{in}$, $F_j$, $F_j^\text{out}$ be respectively the finite components of $s_j^\text{in}$, $s_j$ and $s_j^\text{out}$.

**Remark 8.3.** The main difference between the KLMST algorithm and the abstraction refinement procedure from Section 5.2 lies in the decomposition step. Because some of the ideals $I_\xi$ denoted by the various sequences $\xi$ in $\Xi_n$ might be comparable, a decomposition step (27) might leave $D_n = D_{n+1}$ unchanged. This explains why we cannot use Fact 3.3 to prove termination but rely instead on a ranking function in Section 8.3. It would be interesting to provide a variant of the KLMST decomposition algorithm that follows more closely the abstraction refinement procedure. □
8.2.1. Unpumpable Case. If $s_j^n$ is not forward pumpable by $G_j$, the algorithm of Karp and Miller [23] provides an effective way of computing an index $i \in F_j$ and a constant $c$ such that configurations occurring in any run $\rho$ in $\Omega_M$ are bounded by $c$ on component $i$. The same property holds if symmetrically $s_j^\text{out}$ is not backward pumpable by $G_j$.

In such cases the graph $G_j$ can be synchronised with a finite state automaton $A$ with states in $S = \{0, \ldots, c\}$ and transitions of form $(n, a, m) \in S \times A \times S$ satisfying $m = a(i) + n$. This synchronisation might produce a graph that is no longer strongly connected, but it can be decomposed into strongly connected components. This way we obtain a finite family $\text{dec}(\xi)$ of marked witness graph sequences where the graph $G_j$ in $\xi$ is replaced by sequences of subgraphs of $G_j \times A$ where the finite components $F_j$ of $G_j$ are replaced by a larger set $F_j \cup \{i\}$.

8.2.2. Input/Output Bounded Solutions. Now, let us assume that $\xi$ is not perfect due to the conditions on the set of solutions $L_\xi$. Following the notations introduced in Definition 7.2, recall that we can check in nondeterministic polynomial time whether $\sup X_j(i) < \omega$ for a component $i$ such that $s_j^n(i) = \omega$. If it is not the case, we obtain a component $i \notin F_j^n$ such that $\sup X_j(i) = c$ is finite. Such a bound is computable in deterministic polynomial time. Now, just observe that component $i$ of $s_j^n$ can be replaced by all the possible values up to $c$. We obtain in this way a finite family $\text{dec}(\xi)$ where the set $F_j^n$ is replaced by $F_j^n \cup \{i\}$. The same construction can be applied symmetrically when $\sup Y_j$ does not match $s_j^\text{out}$.

8.2.3. Edge Bounded Solutions. Finally, assume that $\{\psi_j(e) \mid \psi_j \in \Psi_j\}$ is bounded. Once again, we can effectively compute in deterministic polynomial time an upper bound $c$ of this set. Notice that in this case, every run $\rho_j \in \Omega_M$ labelled by a word $\sigma$ provides a cycle on $s_j$ in $G_j$ in such a way that $e$ occurs at most $c$ times. By removing from $G_j$ the edge $e$ we obtain a graph that may not be strongly connected any more. However, by computing strongly connected components, we obtain in this way a finite family $\text{dec}(\xi)$ such that the graph $G_j$ has been replaced by sequences of up to $c$ graphs, each with a set of edges included in $E_j \setminus \{e\}$.

8.3. Ranking Function. We present the usual termination argument for the KLMST algorithm by explicitly giving a ranking function $r$ from marked witness graph sequences into an ordinal, such that $r(\xi) > r(\xi')$ for all $\xi'$ in $\text{dec}(\xi)$.

8.3.1. Ordinals. Rather than the usual multiset ordering over triples in $\mathbb{N}^3$ ordered lexicographically used in the KLMST algorithm, we use an equivalent formulation using ordinals. Recall that an ordinal $\alpha < \varepsilon_0$ can be written in Cantor normal form (CNF) as $\alpha = \omega^{\alpha_1} + \cdots + \omega^{\alpha_n}$ where $\alpha > \alpha_1 \geq \cdots \geq \alpha_n$, or equivalently as $\alpha = \omega^{\alpha_1} \cdot c_1 + \cdots + \omega^{\alpha_n} \cdot c_n$ with $\alpha > \alpha_1 > \cdots > \alpha_n$ and finite $c_i$’s.

One can compare two ordinals $\alpha = \omega^{\alpha_1} + \cdots + \omega^{\alpha_n}$ and $\beta = \omega^{\beta_1} + \cdots + \omega^{\beta_m}$ using their CNFs: $\alpha < \beta$ if and only if there exists $k \leq m$ such that $\alpha_j = \beta_j$ for all $1 \leq j < k$ with $j \leq n$, and $n < k$ or $\alpha_k < \beta_k$.
The natural sum of two ordinals $\alpha = \omega^{\alpha_1} + \cdots + \omega^{\alpha_n}$ and $\beta = \omega^{\beta_1} + \cdots + \omega^{\beta_m}$ is defined as $\alpha \oplus \beta \overset{\text{def}}{=} \omega^{\gamma_1} + \cdots + \omega^{\gamma_{n+m}}$ such that $\gamma_1 \geq \cdots \geq \gamma_{n+m}$ is a reordering of the $\alpha_i$’s and $\beta_j$’s.

8.3.2. Rank of a Marked Witness Graph. We associate with a marked witness graph $M = (s_{\text{in}}, G, s_{\text{out}})$ an ordinal $\beta_M$ in $\omega^3$ defined as

$$\beta_M \overset{\text{def}}{=} \omega^2 \cdot (d - |F|) + \omega \cdot |E| + (2d - |F_{\text{in}}| - |F_{\text{out}}|)$$

(29)

where $G = (S, E, s)$, and $F_{\text{in}}, F, F_{\text{out}}$ are respectively the defined components of $s_{\text{in}}, s, s_{\text{out}}$. Note that this is equivalent to a lexicographic ordering over triples in $\mathbb{N}^3$.

8.3.3. Rank of a Sequence. We associate with a marked witness graph sequence $\xi = M_0, a_1, M_1, \ldots, a_k, M_k$ the ordinal $r(\xi)$ in $\omega^\omega^3$ defined by

$$r(\xi) \overset{\text{def}}{=} \bigoplus_{1 \leq j \leq k} \omega^{\beta_{M_j}}.$$  

(30)

Note that this is equivalent to a multiset ordering over the $\beta_{M_j}$.

8.3.4. Termination Argument. By seeing the KLMST algorithm as constructing a tree with $\xi$ labelling the parent node of $\xi'$ if $\xi$ is imperfect and $\xi' \in \text{dec}(\xi)$, this ranking function shows that the tree has finite height. Since the families $\Xi_0$ and $\text{dec}(\xi)$ are finite, this tree is also of finite degree, and is therefore finite by König’s Lemma.

We establish in this section an $F_{\omega^3}$ upper bound on the complexity of the KLMST decomposition algorithm, which yields the first upper bound on the complexity of VAS reachability. Without loss of generality, we can assume that the actions in $A$ are in $\{-1, 0, 1\}^d$.

9.1. Subrecursive Hierarchies. As noted early on e.g. by Müller [35], the complexity of the decomposition algorithm of Mayr, Kosaraju, and Lambert is not primitive-recursive. As a consequence, we have to employ some lesser known complexity classes in order to express upper bounds on the running time and space of this algorithm.

9.1.1. The Hardy Hierarchy. A convenient tool to this end is found in the Hardy hierarchy of functions. Given some monotone expansive function $h: \mathbb{N} \to \mathbb{N}$, this is an ordinal-indexed hierarchy of functions $(h^\alpha: \mathbb{N} \to \mathbb{N})_\alpha$ defined by transfinite induction by

$$h^0(x) \overset{\text{def}}{=} x, \quad h^{\alpha+1}(x) \overset{\text{def}}{=} h^\alpha(h(x)), \quad h^\lambda(x) \overset{\text{def}}{=} h^\lambda(x)(x),$$

where $\lambda$ denotes a limit ordinal and $\lambda(x)$ the $x$th element of its fundamental sequence. The latter is usually defined for limit ordinals below $\varepsilon_0$ by

$$(\gamma + \omega^{\beta+1})(x) \overset{\text{def}}{=} \gamma + \omega^\beta \cdot (x + 1),$$

$$(\gamma + \omega^\lambda)(x) \overset{\text{def}}{=} \gamma + \omega^\lambda(x).$$

Observe that $h^k$ for some finite $k$ is the $k$th iterate of $h$. At index $\omega$, $\omega(x) = x + 1$ and thus $h^\omega(x) = h^{x+1}(x)$; more generally, $h^\alpha$ is a transfinite
iteration of the function $h$, using a kind of diagonalisation to handle limit ordinals.

**Example 9.1.** For instance, starting with the successor function $H(x) \overset{\text{def}}{=} x + 1$, we see that $H^\omega(x) = H^1(x + 1) = 2x + 1$. The next limit ordinal occurs at $H^{\omega^2}(x) = H^{\omega+1}(x + 1) = H^\omega(2x + 1) = 4x + 3$. Fast-forwarding a bit, we get for instance a function of exponential growth $H^{\omega^2}(x) = 2^{x+1}(x + 1) - 1$, and later a non-elementary function $H^{\omega^3}$, an “Ackermannian” non primitive-recursive function $H^{\omega^4}$, and a “hyper-Ackermannian” non multiply recursive-function $H^{\omega^\omega}$.

9.1.2. **Complexity Classes.** Although we could derive upper bounds in terms of Hardy functions, it is more convenient to work with coarser-grained complexity classes. For $\alpha > 2$, we define respectively the fast-growing function classes $(F_\alpha)$ of Löb and Wainer [33] and the associated fast-growing complexity classes $(F^\alpha)$ by

$$F_\alpha \overset{\text{def}}{=} \bigcup_{\beta < \omega^\alpha} \text{FSpace}(H^\beta(n)), \quad (31)$$

$$F^\alpha \overset{\text{def}}{=} \bigcup_{p \in F_\alpha} \text{SPACE}(h^{\omega^\alpha}(p(n))), \quad F_\omega \overset{\text{def}}{=} F^\omega, \quad (32)$$

where $\text{FSpace}(s(n))$ (resp. $\text{SPACE}(s(n))$) denotes the set of functions computable (resp. problems decidable) in space $O(s(n))$ and $H$ is the successor function $H(x) \overset{\text{def}}{=} x + 1$. This defines for instance $\mathcal{F}_{<\omega}$ as the set of primitive-recursive functions, and $F_\omega$ as the class of problems that can be solved in Ackermann time of some primitive-recursive function of their input size. Here $F^\omega$ is not primitive-recursive, but among the lowest multiply-recursive classes.

9.2. **Length Function Theorems.** Given some wqo $(X, \leq)$, let us posit a norm $|.|_X : X \to \mathbb{N}$ over $X$ such that $X_{\leq n} \overset{\text{def}}{=} \{x \in X \mid |x|_X \leq n\}$ is finite for every $n$. Given a control function $g : \mathbb{N} \to \mathbb{N}$ which is monotone expansive and some initial norm $n \in \mathbb{N}$, we say that a sequence $x_0, x_1, \ldots$ over $X$ is $(g, n)$-controlled if for all $i$, $|x_i|_X \leq g^i(n)$ the $i$th iterate of $g$. Then there exists maximal $(g, n)$-controlled bad sequences over $(X, \leq)$, and we write $L_{g,X}(n)$ for their length.

Length function theorems provide upper bounds on this maximal length $L_{g,X}(n)$. The upper bounds we use from [42] are expressed in terms of another hierarchy of functions called the Cichoń hierarchy $(h_\alpha : \mathbb{N} \to \mathbb{N})_\alpha$. The relation with the Hardy hierarchy is that, if a controlled sequence is of length bounded by some $h_\alpha(x)$ from the Cichoń hierarchy, then the norm of all its elements is bounded by

$$h^{h_\alpha}(x) = h^\alpha(x) \quad (33)$$

in the Hardy hierarchy.

For instance, upper bounds for $(\mathbb{N}^d \times Q, \leq)$ for some finite set $Q$, along with the product ordering, can be found in [42 Theorem 2.34], where the norm of a pair $(x, q)$ from $\mathbb{N}^d \times Q$ is $\max_{1 \leq i \leq d} x(i)$:
Fact 9.2 ([42]). Let \( H(x) \stackrel{\text{def}}{=} x + 1 \) and \( n, d > 0 \). Then \( L_{H, \mathbb{N}^d \times Q}(n) \leq H_{\omega^d \cdot |Q|d}(dn) \leq H_{\omega^{d+1}}(|Q|dn) \).

Proof. Let us first recall the definition of the Cichoń hierarchy of functions for indices \( \alpha < \epsilon_0 \) [7]:

\[
  h_0(x) \defeq 0, \quad h_{\alpha+1}(x) \defeq 1 + h_{\alpha}(h(x)), \quad h^{\lambda}(x) \defeq h_{\lambda(\alpha)}(x).
\]

Consider any control function \( g \), dimension \( d \), finite set \( Q \), and initial norm \( n \). By computing the maximal order type \( \omega^d \cdot |Q| \) of \( \mathbb{N}^d \times Q \), and when provided with a function \( h \) with \( h(dx - d + 1) \geq dg(x) - d + 1 \), we can combine Corollary 2.24 and Theorem 2.34 from [42] to show that

\[
  L_{g, \mathbb{N}^d \times Q}(n) \leq h_{\omega^d \cdot |Q|}(dn - d + 1).
\]

Since we are dealing with VAS actions in \( \{-1, 0, 1\}^d \), our control function \( g \) is \( H(x) \defeq x + 1 \), and we can choose \( h(x) \defeq x + d = H^d(x) \). The statement then follows from the fact that, for such a function \( h \) and assuming \( d > 0 \),

\[
  h_{\alpha}(x) \leq H_{\alpha,d}(x)
\]

for all \( \alpha < \epsilon_0 \) and \( x \), which can be checked by (a somewhat technical) transfinite induction over \( \alpha \).

Another example from [40], Theorem 3.3 is a length function theorem for ordinals below \( \epsilon_0 \), where the norm \( N(\alpha) \) of an ordinal \( \alpha = \omega^{\alpha_1} \cdot c_1 + \cdots + \omega^{\alpha_n} \cdot c_n \) with \( \alpha > \alpha_1 > \cdots > \alpha_n \geq 0 \) and \( \omega > c_1, \ldots, c_n \geq 0 \) is the largest constant that appears in it: \( N(\alpha) \defeq \max_{1 \leq i \leq n} \{ c_i, N(\alpha_i) \} \):

Fact 9.3 ([40]). Let \( \alpha < \epsilon_0 \) be of norm \( N(\alpha) \leq n \). Then \( L_{g,\alpha}(n) = g_{\alpha}(n) \).

9.3. Controlling the KLMST Decomposition. Recall from Section 8.3 that the KLMST algorithm terminates because any descending sequence of ordinals in \( \omega^3 \) is finite. As remarked in Example 3.2, descending sequences over an ordinal are bad sequences. From the previous discussion of length function theorems, in order to apply the bounds from [40] on the norms in bad sequences over \( \omega^3 \), we need to find a control function for any sequence

\[
  r(\xi_0) > r(\xi_1) > \cdots
\]

of ordinals in \( \omega^3 \) found along a branch of the tree described in [8], 3.4.

9.3.1. A Measure on Marked Witness Graph Sequences. Let us write \( \|v\| \defeq \max_{i \in F} v(i) \) for the infinite norm of partial vectors in \( \mathbb{N}_\omega^d \) and \( \|V\| \defeq \max_{v \in V} \|v\| \) for a set \( V \) of partial vectors. Using the norm function \( N \) over \( \epsilon_0 \) defined above on the ordinals in (29) and (30), we see that \( N(r(\xi)) \) is bounded by

\[
  \|\xi\| \defeq \max_{0 \leq j \leq k} (2d, k, |E_j|, \|s^{\text{in}}_j\|, \|s^{\text{out}}_j\|, \|s_j\|)
\]

for \( \xi = M_0, a_1, \ldots, a_k, M_k \) where \( M_j \) is the marked graph \( (s^{\text{in}}_j, G_j, s^{\text{out}}_j) \) and \( G_j = (s_j, E_j, s_j) \). Note that \( \|\xi_0\| = \max(2d, 1, |A|) \) initially.
9.3.2. Controlling Decompositions. We are going to exhibit a control function \( g \) such that \( \|\xi_i\| \leq g(\|\xi_0\|) \) for all descending sequences (34) and index \( i \), which will therefore also be a control function on (34) for the ordinal norm. It suffices to show that \( \|\xi'\| \leq g(\|\xi\|) \) whenever \( \xi' \in \text{dec}(\xi) \). Let us analyse how this measure evolves in the different decomposition cases:

1. In the unpumpable case, the constant \( c \) can be bounded using Fact 9.2 by \( H_{d+1}(d^2\cdot|S_j|\cdot\max(\|s_{j}^\text{in}\|,\|s_{j}^\text{out}\|)) \) (see also [19, Theorem 2.10] or [12, Section VII-C] for similar enough bounds in terms of the fast-growing function \( F_{d+1} = H_{d+1} \)). The resulting sequences \( \xi' \) in \( \text{dec}(\xi) \) satisfy therefore \( \|\xi'\| \leq H_{d+1}(\|\xi\|) \).

2. In the input/output bounded case, the constant \( c \) is at most exponential in the size of the linear system \( L_\xi \), which is of polynomial size in \( \|\xi\| \). Thus \( \|\xi'\| \leq 2^{p(\|\xi\|)} \) for some fixed polynomial \( p \).

3. In the edge bounded case, the constant \( c \) is similarly at most exponential in the size of \( L_\xi \) and again \( \|\xi'\| \leq 2^{p(\|\xi\|)} \) for some fixed polynomial \( p \).

Assuming \( d \geq 1, H_{d+1}(x) > 2^x \), hence we can choose \( g(x) \equiv H_{d+1}(p(x)) \) for some fixed polynomial \( p \) as our control function. This is a primitive-recursive function in \( F_{<\omega} \) for any fixed \( d \), and is in \( F_{<\omega+1} \) when \( d \) is part of the input.

9.4. Complexity Bounds. Assuming \( \|\xi_0\| \geq 3 \), by Fact 9.3 the norm of the elements in any sequence (34) controlled by \( g \) is at most \( g_{\omega^3}(\|\xi_0\|) \). This function can be computed in space \( g_{\omega^3}(e(\|\xi_0\|)) \) for some elementary function \( e \) by [41, Theorem 5.1]. This yields the same bound on the space used by a nondeterministic version of the KLMST decomposition algorithm, which guesses a branch like (34) that leads to a perfect marked witness graph sequence if there is one. Finally, because our function \( g \) yields \( F_{g_{\omega^3}} = F_{\omega^3} \) by [41, Theorem 4.4], we obtain:

**Theorem 9.4.** VAS reachability is in \( F_{\omega^3} \).

9.5. A Combinatorial Algorithm. The bounds in Section 9.4 allow to propose a conceptually simple algorithm for VAS Reachability, based on a small run property. If there is a run in \( \text{Runs}_A(x, y) \), it must belong to some \( \Omega_\xi \) for a perfect \( \xi \) constructed by the KLMST decomposition. Thus this \( \xi \) is of measure \( \|\xi\| \) bounded by \( g_{\omega^3}(\|\xi_0\|) \). Using Lemma 7.3 we can extract a run of commensurate length \( \ell \).

The combinatorial algorithm is a nondeterministic algorithm that first computes \( \ell \) and then guesses a run \( \rho \) in \( \text{Runs}_A(x, y) \) of length at most \( \ell \). Its complexity is similar to that of the KLMST decomposition algorithm, in \( F_{\omega^3} \).

10. Conclusion

The KLMST decomposition algorithm of Mayr, Kosaraju, and Lambert is most certainly a stroke of genius, allowing to prove the decidability of reachability in VAS. What was however sorely lacking until now was an explanation for this decomposition that could be adapted and extended in
various directions. Far from closing the subject, we expect this demystification to span a whole research programme.

The first natural question is how easily one can use the framework of ideals on runs for various VAS extensions. A good test is the case of VAS with hierarchical zero tests, which were proven to enjoy a decidable reachability problem by Reinhardt [36]. A wqo on runs using nested applications of Higman’s Lemma for this extension is defined by Bonnet [6] in his alternative decidability proof using Presburger inductive invariants. Using the algebraic framework of Section 4.3, we see that prerun ideals for this new ordering are essentially nested products, and thus bear at least a superficial resemblance to the structures manipulated by Reinhardt [36]. The framework could also shed new light on reachability in other VAS extensions [28, 39, 27].

A second question is whether we can significantly improve the $F_{\omega^3}$ upper bound provided in Section 9. The best known lower bound on the running time of the algorithm is Ackermannian, i.e. $F_{\omega}$, leaving a huge gap on the complexity of the KLMST algorithm, and a gigantic gap on the complexity of VAS reachability, which is only known to be ExpSpace-hard.

Acknowledgements. The authors thank J. Goubault-Larrecq, P. Karandikar, K. Narayan Kumar, and Ph. Schnoebelen for sharing their draft [16] with us and for insightful discussions around the uses of wqo ideals.

Appendix A. Undecidability of Adherence Membership

**Theorem 5.2.** The adherence membership of prerun ideals is already undecidable for ideals of the form $\downarrow x \times D^* \times \downarrow x$ for $D$ a downward-closed subset of $\text{Trans}_A$ and $x$ in $\mathbb{N}^d$.

The proof proceeds by a reduction from the boundedness problem for lossy Minsky machines, which was shown undecidable by Dufourd et al. [11] (see also the survey [43]).

**Lossy Minsky machines** (LMM) are Minsky machines where counter values might decrease spontaneously at all times. Let us define their syntax and semantics in a style similar to those of VASs. Let $d \in \mathbb{N}$ be the dimension of the machine, i.e. its number of counters. A **Minsky action** $r$ is a pair $(Z, a)$ where $Z \subseteq \{1, \ldots, d\}$ denotes the components tested for zero, and $a$ is a vector in $\mathbb{Z}^d$ satisfying $a(i) = 0$ for every $i \in Z$. We associate with such a Minsky rule $r$ a transition relation $\xrightarrow{r}$ over the set of configurations $\mathbb{N}^d$ defined by $x \xrightarrow{r} y$ if $x(i) = 0 = y(i)$ for every $i \in Z$ and $y = x + a$. A **Minsky machine** is a finite set $R$ of Minsky rules. A Minsky machine $R$ is said to be **lossy** if $(\emptyset, -e_i) \in R$ for every $1 \leq i \leq d$ (where $e_i$ is the unit vector with 1 in coordinate $i$ and 0 everywhere else).

A set $X \subseteq \mathbb{N}^d$ is called a **post-fixpoint** for a Minsky machine $R$ if for every $x \in X$ and $r \in R$ the relation $x \xrightarrow{r} y$ implies $y \in X$. The **reachability set** $\text{Reach}(R, x_{\text{init}})$ of a Minsky machine $R$ from an initial configuration $x_{\text{init}}$ is the minimal post-fixpoint of $R$ that contains the initial configuration.

**Problem:** LMM Boundedness.

**input:** A $d$-dimensional LMM $R$ and an initial configuration $x_{\text{init}}$ in $\mathbb{N}^d$. 
question: Is Reach$(R, x_{\text{init}})$ finite?

As mentioned earlier this boundedness problem is undecidable [11, 43].

**Minimality of Post-Fixpoints.** Note that, due to lossiness, any post-fixpoint is downward-closed and has therefore a finite ideal decomposition using vectors in $\mathbb{N}^d$. The ideal decomposition of Reach$(R, x_{\text{init}})$ is however not effective—or the boundedness problem would be decidable: the machine is unbounded if and only if some $\omega$-value appears in some coordinate of an ideal from the decomposition of Reach$(R, x_{\text{init}})$.

Assume we have an oracle to decide whether a post-fixpoint $X$ that contains $x_{\text{init}}$ is equal to Reach$(R, x_{\text{init}})$. Because we can enumerate finite sets of vectors in $\mathbb{N}^d$ and effectively check whether they define a post-fixpoint $X$ that contains $x_{\text{init}}$, we could use this oracle to construct the ideal decomposition of Reach$(R, x_{\text{init}})$—and as noted just before, use the latter to decide the boundedness problem. This means that we cannot decide whether a post-fixpoint is equal to Reach$(R, x_{\text{init}})$—this is similar to [43, Theorem 3.7]:

**Problem:** Minimality of LMM Post-Fixpoints.

input: A $d$-dimensional LMM $R$, an initial configuration $x_{\text{init}}$ in $\mathbb{N}^d$, and a post-fixpoint $X$ that contains $x_{\text{init}}$.

question: Does $X = \text{Reach}(R, x_{\text{init}})$?

This problem is already undecidable for a slightly restricted class of LMMs: Observe that if $x_{\text{init}} = 0$ then the reachability set is infinite if, and only if, there exists $(Z, a) \in R$ for some $Z$ such that $a > 0$. So, we can assume in the previous problem that $x_{\text{init}} \neq 0$. Observe similarly that if $(Z, x_{\text{init}}) \in R$ for some $Z$ (where necessarily $x_{\text{init}}(i) = 0$ for all $i \in Z$ by assumption on Minsky actions), then $n x_{\text{init}}$ is reachable for every $n \in \mathbb{N}$ and by the previous assumption the reachability set is infinite. So we can also assume that for every $(Z, a) \in R$ we have $a \neq x_{\text{init}}$ and retain undecidability.

**Proof of Theorem 5.2.** We are going to reduce the problem of testing the minimality of LMM post-fixpoints to the adherence membership problem for an ideal of the form $\downarrow x_{\text{init}} \times D^* \times \downarrow x_{\text{init}}$ where $D$ is a downward-closed set of transitions. The main intuition is that a downward-closed set of transitions where some maximal transitions have zero components can be used to perform zero tests in a VAS, and simulate the behaviour of a lossy Minsky machine.

Without loss of generality, we assume that $(\emptyset, 0)$ belongs to $R$ since the reachability set is unchanged by adding this Minsky rule. Let $X \subseteq \mathbb{N}^d$ be a post-fixpoint of $R$ that contains the initial configuration $x_{\text{init}}$. By minimality of Reach$(R, x_{\text{init}})$ we get Reach$(R, x_{\text{init}}) \subseteq X$. We define a downward-closed set $D_X$ of transitions of some VAS $A$ in such a way that the inclusion Reach$(R, x_{\text{init}}) \subseteq X$ is an equality if, and only if, the set of preruns $(x_{\text{init}}, w, x_{\text{init}})$ with transition sequence $w \in D_X$ is an ideal from $\text{Idl}(\text{Runs}_A(x_{\text{init}}, x_{\text{init}}))$.

Our VAS is defined by

$$A \overset{\text{def}}{=} \{ x_{\text{init}} \} \cup \{ a \mid \exists Z. (Z, a) \in R \} .$$

(36)
Our set $D_X$ is defined as the set of transitions

$$D_X \overset{\text{def}}{=} \{(0, x_{\text{init}}, x_{\text{init}})\}$$

$$\cup \{(x, a, y) \in X \times A \times X \mid \exists \exists r = (Z, a) \in R. x \xrightarrow{r} y\}, \quad (37)$$

which is downward-closed because $X$ is, and we let $I_X$ denote the following set of preruns using transitions from $D_X$, which is an ideal of $\text{PreRuns}_A$:

$$I_X \overset{\text{def}}{=} \downarrow x_{\text{init}} \times D_X^* \times \downarrow x_{\text{init}}. \quad (38)$$

Note that a representation of $I_X$ can effectively be computed from a representation of $X$.

**Claim 1.** $\text{Reach}(R, x_{\text{init}})$ is the set of configurations $x \in \mathbb{N}^d$ such that there exists a run $(x_{\text{init}}, w, x)$ with $w \in D_X^*$. The proof is by induction on the length of runs $(x_{\text{init}}, w, x)$ of $A$ and runs $x_{\text{init}} \xrightarrow{w} x$ of $R$.

**Claim 2.** If $X = \text{Reach}(R, x_{\text{init}})$ then $I_X$ is in the adherence of $\text{Runs}_A(x_{\text{init}}, x_{\text{init}})$.

Let $t = (x, a, y)$ be a transition in $D_X$. By definition $x \in X = \text{Reach}(R, x_{\text{init}})$ and we deduce by Claim 1 that there exists a run $(x_{\text{init}}, w_t, x)$ with $w_t \in D_X^*$. Due to lossiness, there also exists a run with transition sequence $w'_t$ in $D_X^*$ from $y$ to $0$ labelled by actions $-e_i$. By definition (37) the transition $t_{\text{init}} \overset{\text{def}}{=} (0, x_{\text{init}}, x_{\text{init}})$ belongs to $D_X$. Hence for every $t \in D_X$ there exists a run with transition sequence $w_tw'_t$ in $D_X^*$ from $x_{\text{init}}$ to $x_{\text{init}}$ along which $t$ occurs.

By concatenating such transition sequences, for every word $w = t_1 \cdots t_k$ of transitions $t_1, \ldots, t_k \in D_X$, there exists a run from $x_{\text{init}}$ to $x_{\text{init}}$ with transitions in $D_X^*$ and with $w$ as an embedded subsequence. We conclude by noting that these runs form a directed subset of $\text{Runs}_A(x_{\text{init}}, x_{\text{init}})$.

**Claim 3.** If $I_X$ is in the adherence of $\text{Runs}_A(x_{\text{init}}, x_{\text{init}})$ then $X = \text{Reach}(R, x_{\text{init}})$.

Assume there exists a directed family $\Delta$ of runs with $\downarrow \Delta = I_X$. Let $x \in X$; let us show that $x \in \text{Reach}(R, x_{\text{init}})$. The prerun $(x_{\text{init}}, w, x_{\text{init}})$ with

$$w \overset{\text{def}}{=} (0, x_{\text{init}}, x_{\text{init}})(x, 0, x) \quad (39)$$

belongs to $I_X$ (recall that we assumed $(0, 0) \in R$). Hence there exists a run $\rho = (x_{\text{init}}, w', x_{\text{init}})$ in $\Delta$ with $w \leq_s w'$ (for the subsequence embedding over $(\mathbb{N}^d \times A \times \mathbb{N}^d)^*$). Thus $w'$ is in $D_X^*$ and of the form

$$w' = w_1(y, x_{\text{init}}, y + x_{\text{init}})w_2(x + z, 0, x + z)w_3 \quad (40)$$

for some vectors $y$ and $z$ in $\mathbb{N}^d$. Because $(Z, x_{\text{init}}) \notin R$ for any $Z$, $y = 0$.

Therefore $(x_{\text{init}}, w_2, x + z)$ is a run with transitions in $D_X$. Hence by Claim 1, $x + z$ is in $\text{Reach}(R, x_{\text{init}})$, and by lossiness $x$ is also in $\text{Reach}(R, x_{\text{init}})$. This shows $X \subseteq \text{Reach}(R, x_{\text{init}})$ and thus $\text{Reach}(R, x_{\text{init}}) = X$. \qed
