SYNOPSIS. In rainbow trout the magnitude of the cortisol response to stress shows both consistency over time and a moderate to high degree of heritability, and high responding (HR) and low responding (LR) lines of rainbow trout have been generated by individual selection for consistently high or low post-stress cortisol values. Using 2nd and 3rd generation fish, we tested the hypothesis that differential stress responsiveness is associated with behavioral alterations in the HR-LR trout model. LR fish showed a tendency to become socially dominant, a rapid recovery of food intake after transfer to a novel environment, and a reduced locomotor response in a territorial intrusion test. Furthermore, stress induced elevation of brain stem and optic tectum concentrations of the monoamine neurotransmitters serotonin, dopamine, and norepinephrine and their metabolites suggests that both synthesis and metabolism of these transmitters were elevated after stress to a larger degree in HR than in LR trout. A divergent pattern was seen in the hypothalamus, where LR fish displayed elevated levels of 5-hydroxyindoleacetic acid (a serotonin metabolite) and 3-methoxy-4-hydroxyphenylglycol (a norepinephrine metabolite). Thus, selection for a single trait, cortisol responsiveness, in rainbow trout is associated with concurrent changes in both behavior and central signaling systems. The apparent parallel to genetically determined stress coping styles in mammals, and the existence of similar trait associations in unselected populations of rainbow trout, suggests an evolutionarily conserved correlation between multiple traits. Continuing studies on the HR and LR trout lines are aimed at providing the physiological and genetic basis for new marker-assisted selection strategies in the rapidly developing finfish aquaculture industry, as well as increased knowledge of the function and evolution of central neuroendocrine signaling systems.

INTRODUCTION

The rainbow trout *Oncorhynchus mykiss* is native to the Pacific coast of North America and Russia, but has been widely cultivated and introduced as a food and game fish in temperate regions around the world. Wide occurrence, availability and ease of culture have made the rainbow trout one of the most intensively studied fish species in biological research—this species has been used in fields ranging from evolutionary ecology to behavior, physiology, genetics, toxicology and cancer research (see Thorgaard *et al.*, 2002). Rainbow trout also attracts interest as a model species for the commercially important family salmonidae, with focus on nutrition, reproduction, and stress physiology.

Intensive aquaculture of rainbow trout and other salmonids is a relatively new innovation, compared to the cultivation of most other animals. The process of domestication has only just begun in salmonids, and considerable effort is devoted to selecting for and defining the heritability of economically important traits in these fish, such as growth rate, age at maturity, fillet composition, and disease resistance (see *e.g.*, Gall and Huang, 1988*a, b*; Gjerde, 1993; Gjøen and Bentsen, 1997; Gjedrem, 2000; Midtlyng *et al.*, 2002). Natural

populations of salmonids are characteristic in displaying an immense variability in genetic composition, life history, and a range of phenotypic traits (Ryman, 1983; Taylor, 1991; Hershberger, 1992; Carlsson *et al.*, 1999; Waples *et al.*, 2001; Hansen *et al.*, 2002), which makes these fish excellent raw material for genetic studies and selection experiments.

Fish under intensive culture conditions are exposed to a regime of acute and chronic stressors, which have adverse effects on growth, reproduction, immunocompetence, and flesh quality, among other things (Barton *et al.*, 1987; Maule *et al.*, 1989; Barton and Iwama, 1991; Lowe *et al.*, 1993; Pickering, 1993; Balm, 1997; Pankhurst and Van der Kraak, 1997; Sigholt *et al.*, 1997; Schreck *et al.*, 2001). As in other vertebrates, the blood concentration of corticosteroid hormones is a major index of stress in fish, and elevated levels of these hormones arise from activation of the hypothalamus-pituitary-interrenal (HPI) axis (Wendelaar-Bonga, 1997). The main corticosteroid in teleost fish is cortisol (Kime, 1987), and this steroid is a causal factor in many of the deleterious effects of stress (Barton *et al.*, 1987; Barton and Iwama, 1991; Harris and Bird, 2000; Pankhurst and Van der Kraak, 2000; Schreck *et al.*, 2001; Consten *et al.*, 2002; Bernier *et al.*, 2004). In rainbow trout the magnitude of the cortisol response to stress is an individual characteristic which is stable over time, with a moderate to high degree of heritability (Pottinger *et al.*, 1992, 1994; Fevolden *et al.*, 1999). Thus, post-stress cortisol levels provide a trait

of functional and economical significance upon which selection pressure can be directed, and lines of high- (HR) and low-responsive (LR) trout have been established at the Windermere laboratory of the UK Centre for Ecology and Hydrology (Pottinger and Carrick, 1999, 2001a).

In association with the physiological response, stress may lead to drastic changes in behavior, which has been classified and interpreted in various ways (see *e.g.*, Koolhaas *et al.*, 1999; Wingfield, 2003). A distinction is often made between proactive (active coping, or “fight or flight”) and reactive (passive coping, or “conservation-withdrawal”) responses (Engel and Schmale, 1972; Henry and Stephens, 1977; Benus *et al.*, 1991a; Henry, 1993; Koolhaas *et al.*, 1999). In both mammals and fish, a transition from behavioral activation to an inhibiting effect is often seen with increasing duration or severity of the challenge (Haller *et al.*, 1998; Øverli *et al.*, 2004a). Seminal studies in mammals indicated that the threshold at which the shift from an active to a passive behavioral response occurs is subject to great individual variation (Engel and Schmale, 1972; Henry and Stephens, 1977).

More recently, it has been established that individual differences in the physiological stress response are associated with differences in behavior. For instance, a pro-active stress coping style is behaviorally characterized by a high level of active avoidance, aggression, and other behavioral patterns indicating an active attempt to counteract the stressful stimulus (*e.g.*, defensive burying in rodents) (Bohus *et al.*, 1987; Benus *et al.*, 1989, 1991a; Sluyter *et al.*, 1996). Reactive (passive) coping, on the other hand, involves immobility and low levels of aggression. Physiologically, the proactive strategy is associated with low hypothalamus-pituitary-adrenal axis (HPA axis, the mammalian equivalent of the teleost HPI axis) responsiveness, but high sympathetic reactivity, while the opposite is true for reactive coping (de Boer *et al.*, 1990; Korte *et al.*, 1992; Fokkema *et al.*, 1995). A genetic basis for the expression of behavioral and physiological components of individual coping styles has repeatedly been demonstrated (*e.g.*, Driscoll *et al.*, 1998; Ellenbroek and Cools, 2002; de Boer *et al.*, 2003; Veenema *et al.*, 2003). Limited information, however, is available on whether different behavioral-physiological stress coping styles are present in teleost fish (but see Francis, 1990; Van Raaij *et al.*, 1996; Budaev *et al.*, 1999).

In fish, like in other vertebrates, behavioral and physiological stress responses are to a large degree linked by common control mechanisms in the brain, and the monoamine neurotransmitters serotonin (5-hydroxytryptamine, 5-HT), dopamine (DA), and norepinephrine (NE) play a vital role in this co-ordination (Winberg and Nilsson, 1993; Winberg *et al.*, 1997, 2001; Øverli *et al.*, 1998, 1999; Höglund *et al.*, 2001, 2002a, b; Lepage *et al.*, 2002, 2003; Clements *et al.*, 2003; Larson *et al.*, 2003; Perreault *et al.*, 2003). Genetically determined variation in behavior and stress responsiveness has been associated with differences in

brain monoaminergic function in both fish and mammals (*e.g.*, Benus *et al.*, 1991b; Popova *et al.*, 1991a, b; Nikulina *et al.*, 1992; Rots *et al.*, 1996a, b, c; de Kloet *et al.*, 1996; Sallinen *et al.*, 1999; Lepage *et al.*, 2000; Giorgi *et al.*, 2003). In this paper we review the effects of selection for post stress cortisol production in rainbow trout, with particular reference to a series of studies investigating the association between altered plasma cortisol dynamics, behavior, and brain monoamine neurotransmitters. In other words, we examine the hypothesis that behavioral and physiological traits are linked in such a way that altering one trait, post-stress plasma cortisol concentrations, incurs differences in other putative components of individual stress coping styles. It should be noted that several additional physiological differences between HR and LR lines, such as metabolic changes and interrenal sensitivity to adenocorticotrophic hormone (ACTH) also has been reported, but for details of this experimental work we refer to the original papers (Pottinger and Carrick, 2001b; Trenzado *et al.*, 2003).

MATERIAL AND METHODS

Generation of HR and LR trout lines

The selection procedure and the effect of the breeding program on the cortisol response has been thoroughly described elsewhere (Pottinger and Carrick, 1999, 2001a), and will only be briefly reviewed here. The parental generation of the HR and LR trout lines was established in 1996 by repeated stress testing (3 hr confinement in 50 liter water in groups of 6–7 individuals once monthly) of passive integrated transponder (PIT) tagged 2-year-old rainbow trout. Following confinement, blood samples (0.5 ml) and PIT-tag readings were obtained from anaesthetized (2-phenoxyethanol, 1:2,000) fish, and plasma was later analyzed for cortisol content by a previously validated radioimmunoassay (RIA) procedure (Pickering *et al.*, 1987). The mean post-stress plasma cortisol content across five episodes of confinement was then calculated for each fish, and individuals were ranked accordingly. Between testing fish had been kept in groups of 25 in 1,500 liter holding tanks, and the four most high-responding (HR) and the four most low-responding (LR) fish in each tank were removed from their home tank, segregated by sex, and kept separate in 4 tanks based on group and sex until maturation.

Confinement stress testing of the 1st generation offspring (F1), consisting of 15 HR and 14 LR families each resulting from a unique male-female crossing, were carried out on five different occasions between September 1997 and September 1998, and on five occasions in 1999. A highly significant regression of mid-parent cortisol response on progeny response was seen (estimated r^2 [h²] value = 0.41) and the six LR families with the lowest mean cortisol response and the six HR families with the highest mean cortisol response were identified and used for further work (Pottinger and Carrick, 1999). An unselected (US) popu-

lation resulting from random breeding of fish not designated as HR or LR in the parental group (6 families) was tested on one occasion, and showed a cortisol response intermediate to the mean of these most divergent HR and LR groups. Adult female F1 generation HR and LR fish were later used in a study investigating the effect of selection for stress responsiveness on behavior and brain monoamine neurotransmitters (Øverli *et al.*, 2001, 2002a).

The 2nd generation of offspring consisted of 11 HR, 11 LR and 3 US families. The regression of midparent ($[\text{male} + \text{female}]/2$) cortisol response on progeny cortisol response provided an estimated h^2 of 0.6 in this generation, while male and female parent–progeny regressions provided estimates for h^2 of 0.73 and 0.44, respectively (Pottinger and Carrick, 2001a).

Behavioral experiments

Locomotor activity, feed intake, and brain monoaminergic activity in HR and LR trout. These experiments are described in detail in Øverli *et al.* (2001, 2002a). Recovery of feed intake after transfer to a new and potentially stressful environment was used as an index of adaptiveness. Only adult female F1 fish were available for these studies. Locomotor activity when in isolation and in response to a territorial intruder was also analyzed, along with basal and stress-induced brain 5-HT, DA and NE activity. During April 2000 adult F1 female HR ($n = 18$) and LR ($n = 18$) rainbow trout weighing 987.5 ± 39.5 g (mean \pm SE) were transferred individually from communal holding tanks to rearing in isolation in white 250 liter polypropylene observation tanks. From day 1 after transfer to housing in isolation, fish were fed daily by hand (1.5% of body weight), and fish were observed for 3 min after distribution of food to register food intake. Behavioral observations and blood sampling (see below) were carried out between 10.00 and 14.00.

After being held for 6 days in isolation, locomotor activity was quantified by observing time spent moving during 20 min for each fish, starting 1 hr after feeding. Locomotor activity was quantified again the next day, this time for 20 min immediately following the introduction of an intruder fish in the observation tank. Intruder fish were smaller ($<50\%$ body weight of the resident fish) group reared rainbow trout from a hatchery population, and previously unfamiliar to the test fish.

On the day after the intruder test, 50% of the fish from each line (HR, LR) were randomly selected for individual stress testing in 50 liter confinement tanks. After 1 hr in the confinement tanks, fish were netted, anaesthetized in 0.5 ml/liter 2-phenoxyethanol, and a blood sample was obtained from the caudal sinus into a heparinized syringe. The remaining 50% of the fish were sampled directly from observation tanks to serve as undisturbed controls. Immediately following blood sampling fish were killed by decapitation and dissected, and the presence or absence of food in the stomach and/or intestines was registered. Brains were removed

and dissected into telencephalon (excluding the olfactory bulbs), hypothalamus (excluding the pituitary), optic tectum, and brain stem (excluding the cerebellum). Brain samples were immediately wrapped in aluminum foil and snap frozen in liquid nitrogen, where after concentrations of monoamines and monoamine metabolites in brain samples were analyzed by HPLC with electrochemical detection (Øverli *et al.*, 1999). Plasma cortisol levels were determined using the RIA procedure described by Pickering *et al.* (1987).

Tests for social dominance in HR and LR trout. Tests to investigate the relative tendency toward dominant or subordinate social status of the HR and LR lines were carried out in September and October 2000 using juvenile F2 progeny (Pottinger and Carrick, 2001a). Mixed-sex juvenile fish were used in these tests since they are generally more territorial than adults, and there is no effect of sex on the ability to gain dominance at this life stage (Ø. Øverli and S. Winberg, unpublished results). Dyadic contests were performed following broadly the protocol of Øverli *et al.* (1999). In all, 47 size matched pairs consisting of 1 HR and 1 LR individual were transferred from holding tanks to rearing in glass observation aquaria (63 liter volume) covered with black plastic on three sides. In each aquarium two fish were kept separate by a removable opaque plastic barrier.

Fish were offered food (five crumbs, Trouw Fry 18) twice each day after being transferred to the aquaria. Previous experiments have shown that holding juvenile salmonid fish in isolation for approximately one week with sufficient access to food is highly effective in inducing territoriality and motivation to express aggressive behavior (Winberg *et al.*, 1991; Winberg and Lepage, 1998; Øverli *et al.*, 1999). Barriers separating HR/LR pairs were removed after 5 days of acclimation, resulting in escalated contests for social dominance within each pair. Behavioral observations started at 3 hr after the onset of interaction, by which time the conflict was resolved and the identity of the dominant and subordinate individuals within each pair was clear. At this time dominant fish were characterized by holding a midwater position, displaying extensive movement around the tank, nipping and/or chasing the subordinate, and intercepting food. Subordinate fish were typically located on the base of the aquarium, usually immediately adjacent to the aquarium wall, exhibited little swimming activity, and directed no aggressive acts toward the dominant individual. After 5 hr of social interaction fish were killed and, a blood sample was obtained, and blood plasma was analyzed for cortisol content using a RIA with ethyl acetate extraction (Pottinger and Carrick, 2001a).

RESULTS AND DISCUSSION

Cortisol responsiveness in HR and LR rainbow trout

Post-stress blood plasma cortisol levels of HR and LR trout for every occasion on which they were tested, from the establishment of the parental generation (F0)

FIG. 1. Post-stress blood plasma cortisol levels (mean \pm SE) of LR and HR rainbow trout (mixed sex samples) for all test occasions from the establishment of the parental generation (F0) up to present (F3).

up to present (F3), is shown in Figure 1. There is considerable variation in the magnitude of the cortisol response over time, and between generations, but a difference between the lines (HR > LR) is always evident. The exception to this is the final sample for the F0 fish in which reproductive status may have confounded the normal previously observed divergence. Some of the variation in overall magnitude of the stress response can no doubt be accounted for by seasonal changes in water temperature (Sumpter *et al.*, 1985; Barton and Schreck, 1987; Pickering and Pottinger, 1987) and in reproductive status of the fish (Pottinger *et al.*, 1995; Pottinger and Carrick, 2000). However, it must be borne in mind that these tests were carried out for a variety of purposes and did not employ exactly the same protocol on each occasion. Therefore, while it is appropriate to conclude that divergence in stress responsiveness has been sustained across three generations, it is not possible to directly compare successive time points and evaluate temporal trends.

Notwithstanding this caveat, the type of test that were employed for the first occasion on which each generation was assessed were similar and the results of these tests may be directly compared. The magnitude of the difference in cortisol responsiveness between lines has remained similar over 3 successive generations for juvenile fish subjected to their first stress test (age 6–7 months, tested in September 1997, September 2000 and October 2003). The post-stress

plasma cortisol levels in HR juveniles represents 135%, 224%, and 220% that of the LR fish for the F1–F3 generations respectively. The similarity in the magnitude of divergence of these generations might indicate that there are physiological constraints on the range of plasma cortisol responsiveness to stress in trout. Such constraints may be imposed upon low-responders by the need to retain a functional cortisol response and upon high-responders by problems associated with hypercortisolism.

Finally, it should be noted that strain differences in plasma cortisol levels was never observed in unstressed fish. Thus, it seems likely that the effect of the selection program on post-stress levels of cortisol represents divergent responses to stressors, rather than differences in basal HPI-axis activity, which in turn could affect responsiveness.

Behavioral effects of selection for stress responsiveness

Pottinger and Carrick (2001a) reported a tendency of LR fish to establish social dominance over HR fish when held in pairs (Fig. 2), and Øverli *et al.* (2001) observed that only LR fish had regained feed intake within one week after transfer to a new environment (Fig. 3). Interestingly, an association between rapidly regaining feed intake after environmental change and the ability to win fights for social dominance was also observed in an unselected population of rainbow trout, using juvenile fish of both sexes (Øverli *et al.*, 2004b). These observations indicate that the HR and LR lines are based on multi-trait phenotypes that display a significant amount of variation also in unselected populations, but it has not yet been studied whether the divergence in behavior has increased with successive generations.

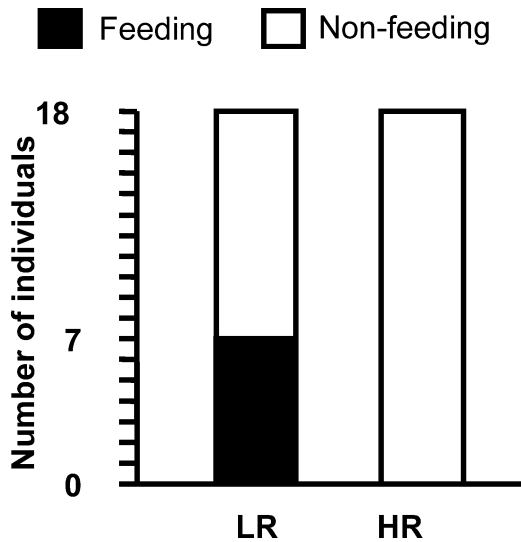

FIG. 3. The number of LR and HR rainbow trout regaining feed intake within 1 week of transfer to a new environment. LR feeding > HR feeding, $P = 0.003$, χ^2 test (data from Øverli *et al.*, 2002a).

Locomotor activity in isolated HR and LR female rainbow trout, when held alone and when challenged with a conspecific intruder, is depicted in Figure 4. HR rainbow trout displayed higher locomotor activity than LR trout in the presence of an intruder, but there was no significant difference between the two groups in the isolated condition. However, both HR and LR rainbow trout increased their activity level when the intruder was present. Thus, it appears that some behavioral differences between HR and LR lines occur only under an acute challenge, which may indicate that they depend on control mechanisms activated in synchronization with the physiological stress response.

Brain monoaminergic activity in HR and LR trout

Concentrations of the three monoamine neurotransmitters 5-HT, DA, and NE and their respective metabolites 5-hydroxyindoleacetic acid (5-HIAA), 3,4-dihydroxyphenylacetic acid (DOPAC), and 3-methoxy-4-hydroxyphenylglycol (MHPG), and corresponding metabolite/monoamine ratios in four different brain regions of stressed and control HR and LR trout are shown in Table 1. Since monoamine neurotransmitters are not exposed to monoamine oxidase (MAO) while stored in vesicles, increased concentrations of their deaminated metabolites are thought to indicate increased release and turnover of the neurotransmitter (Fillenz, 1993).

In particular, metabolite/monoamine ratios are frequently used as an index of neural activity. However, attention should be paid to the fact that altered metabolite/monoamine ratios may be caused by changes in the concentrations of monoamine neurotransmitters as well as metabolites, or by combinations of such changes. Thus, differential patterns of activation may be assumed depending on whether concentrations or ratios are studied. For instance, brain stem 5-HIAA concen-

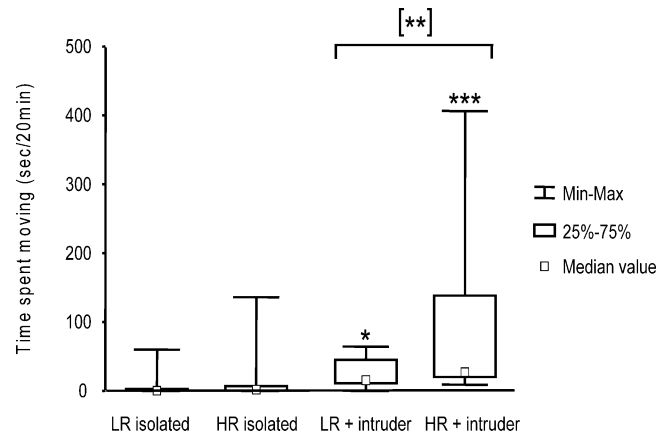

FIG. 4. Locomotor activity in HR and LR rainbow trout quantified as time spent moving during a 20 min observation period, with or without the presence of a conspecific intruder. Asterisks indicate an effect of the intruder, asterisks in brackets [*] indicates a difference between HR and LR fish, * = $P < 0.01$, ** = $P < 0.001$, *** = $P < 0.0001$, Kruskal-Wallis analysis of variance followed by group-wise comparisons by the Mann-Whitney U -test (data from Øverli *et al.*, 2002a).

trations were significantly affected by confinement stress only in HR fish (Table 1). Therefore, it could be concluded that the brain 5-HT system was activated by confinement stress to a larger extent in HR than in LR fish. On the other hand, brain stem 5-HIAA/5-HT ratios were higher in LR than HR fish both in the control condition and after stress. This apparent contradiction is probably caused by the fact that HR fish, but not LR fish, responded to stress by an increase in 5-HT concentrations in the brain stem. Apart from that, three possible explanations can be given to the observation that 5-HIAA/5-HT ratios were elevated in LR fish relative to HR fish: 1. The proportion of 5-HT that was actually released, and thereby exposed to the action of MAO after re-uptake from the intercellular space, was greater in LR fish. 2. MAO enzyme activity was decreased in HR fish. 3. Re-uptake of 5-HT was more effective in LR fish.

Nonetheless, one of the most evident findings of this study was that HR trout reacted to stress by an increase in the tissue concentrations of serotonin (brain stem), dopamine (brain stem), and norepinephrine (optic tectum, telencephalon), whereas low-responsive fish did not (Table 1). Brain stem and optic tectum concentrations of monoamine metabolites were also elevated after stress in HR, but not in LR fish. A divergent pattern was seen in the hypothalamus, where LR fish displayed elevated levels of 5-HIAA and MHPG. Both populations had elevated telencephalic concentrations of these metabolites after stress. Some differences were also seen in fish sampled directly from rearing in isolation, suggesting that the rearing environment was not entirely optimal, and the experimental fish may have experienced a mild stress even in the undisturbed condition. This notion is also in line with the lack of aggressive behavior and low level of feed intake in these fish (Øverli *et al.*, 2002a). Alternatively, differential

stress responsiveness in HR and LR fish is associated with permanent differences in brain monoaminergic systems that are expressed even in unstressed individuals.

Correlated physiological and behavioral stress responses in HR and LR trout lines

The creation of HR and LR lines of rainbow trout confirm that the magnitude of the cortisol response to a standardized stressor is an individual, heritable characteristic in this species (Pottinger *et al.*, 1992, 1994; Fevolden *et al.*, 1999). Furthermore, it appears that the magnitude of stress-induced elevation of blood cortisol is part of a complex trait incorporating several correlated physiological and behavioral responses (Pottinger and Carrick, 2001a, b; Øverli *et al.*, 2001, 2002a; Trenzado *et al.*, 2003). Taken together, these obser-

vations suggest that the HR and LR rainbow trout may represent selection for different physiological/behavioral stress-coping styles, as defined by Koolhaas *et al.* (1999, p. 925). These authors stated: "A coping style can be defined as a coherent set of behavioral and physiological stress responses which is consistent over time and which is characteristic to a certain group of individuals."

As noted previously, the plasma cortisol response is an individual trait which is consistent over time in rainbow trout (Pottinger *et al.*, 1992; Pottinger and Carrick, 1999). The degree to which behavioral traits are consistent in individual HR and LR fish has not been determined, but comparisons of behavior between the two lines have revealed several striking differences (*c.f.*, Figs. 2–4). Behavioral and physiological stress responses are to a large degree controlled by

common neuroendocrine signaling systems. Thus, if the cortisol response is a consistent individual trait, it seems likely permanent differences exist with respect to the behavioral components of different stress coping styles.

Most likely, some degree of trait associations exist in all animals with respect to a fundamental response such as stress coping, but the evolutionary success of different profiles may vary between species. It is not clear whether the behavioral and endocrine traits of LR and HR rainbow correspond exactly to the proactive (active) and reactive (passive) coping styles described in mammals. The proactive stress coping style in rodents involves low glucocorticoid production (de Boer *et al.*, 1990; Korte *et al.*, 1992; Fokkema *et al.*, 1995), while in HR trout high cortisol responsiveness was associated with increased swimming activity during an intruder test (Fig. 4). The impression of the observers was that the HR trout showed anxiety-like erratic behavior, rather than targeted attempts to actively cope with the experimental situation. If that is the case, the behavioral strategy of the LR fish (to remain passive and ignore the presence of an intruder in a low-quality territory) may be more equivalent to the active coping style that is normally associated with low HPA axis responsiveness in rats (Koolhaas *et al.*, 1999). Furthermore, the observation that LR trout tend to win encounters for social dominance (Fig. 2) is in accordance with an active coping style (see *e.g.*, Verbeek *et al.*, 1996; Klomberg *et al.*, 2002; Zhukov and Vinogradova, 2002).

Several rodent models consisting of two contrasting lines/strains that respond differently to stressful environments have also been developed through bidirectional selection. Examples are the Roman high (RHA) and low (RLA) avoidance rats (Driscoll *et al.*, 1998; Steimer and Driscoll, 2003), the Wistar high (HAB) and low (LAB) anxiety-related behavior lines (Liebsch *et al.*, 1998; Yilmazer-Hanke *et al.*, 2004), the Maudsley reactive and nonreactive strains (Blizard and Adams, 2002), the short (SAL) and long attack latency (LAL) house mice (Veenema *et al.*, 2003), apomorphine susceptible and unsusceptible rats (Ellenbroek and Cools, 2002), and several others (*e.g.*, Klomberg *et al.*, 2002; Viggiano *et al.*, 2002, 2003; Brush, 2003; Ramos *et al.*, 2003).

Like the HR and LR rainbow trout, these models were created by selective mating of animals with the highest and lowest scores for a given behavioral or physiological trait over several generations. In general, it is assumed that maximizing differences in this way produces one line with more genes that affect the selected trait positively, and one line carrying more genes with negative effects on the same trait (Ramos and Mormède, 1998; Crabbe, 1999). Ideally, correlated responses should be consistent across several replicate lines to indicate the presence of genetic correlations (Henderson, 1997). Thus, in the case of the HR and LR trout lines, founder effects, unique mutations and random genetic drift can not be ruled out as contrib-

uting factors in the simultaneous divergence of multiple traits. However, the apparent parallel to genetically determined stress coping styles in mammals, and the existence of similar trait associations in unselected populations (Øverli *et al.*, 2004b), suggest an evolutionarily conserved correlation between multiple traits.

Neuroendocrine mechanisms integrating physiological and behavioral stress responses

The mechanisms integrating the behavioral and physiological characteristics of HR and LR trout lines remain largely unknown. The behavioral differences between HR and LR trout are consistent with some reported effects of corticosteroid hormones in poikilotherms (decreased appetite: Gregory and Wood, 1999; increased locomotor activity: Cash and Holberton, 1999; Øverli *et al.*, 2002b). In fish, like in mammals, these steroids typically have time-, context-, and dose-dependent effects (Øverli *et al.*, 2002b; Bernier *et al.*, 2004). Thus, altered competitive ability in a stressful situation such as a fight for social dominance (Pottinger and Carrick, 2001a) may also be directly caused by differences in circulating hormone levels.

The behavioral and physiological characteristics of HR and LR rainbow trout may also be functionally linked through a number of factors which influence both endocrine and behavioral responses. For instance, it seems likely that corticotrophin releasing hormone (CRH) is involved in the increase in locomotor activity observed in HR trout. In juvenile chinook salmon (*Oncorhynchus tshawytscha*), intracerebroventricular injections of CRH induced hyperactivity, an effect that was shown to depend on concurrent (*i.e.*, CRH induced) 5-HT activation (Clements *et al.*, 2003).

Interestingly, CRH administration also increases DA concentrations in dorsal medial hypothalamus of newts (*Taricha granulosa*) (Lowry *et al.*, 2001), and one of the main neurochemical differences between HR and LR rainbow trout was that HR fish responded to stress by increased DA concentrations and turnover in several brain areas, while LR fish did not (Table 1). Genetically determined differences in DA systems has been reported in several other models (Rots *et al.*, 1996a, b, c; Lecca *et al.*, 2004). However, increased DA synthesis and release may also be an effect of acute elevations in glucocorticoid concentrations (Dunn *et al.*, 1978; Piazza *et al.*, 1996a, b; Barrot *et al.*, 2000, 2001). Effects of glucocorticoids on dopaminergic activity are also strongly context (Piazza *et al.*, 1996b) and regionally dependent (Lucas *et al.*, 1998; Barrot *et al.*, 2000, 2001). Thus, at present it is not known whether differences in DA systems between HR and LR trout are a cause or a consequence of hormone dynamics, but there is an interesting parallel to mammalian models which suggest the presence of evolutionary conserved trait correlations. Notably, a similar negative relationship between DA reactivity, stressor or novelty-induced locomotor activity, and social competitive ability has also been demonstrated in cynomolgus monkeys (*Macaca fascicularis*) (Morgan

et al., 2000). Individually housed monkeys with high levels of locomotion in an open-field test after a low dose of cocaine (which increases CNS dopamine) were more likely to become subordinate in subsequent group housing (Morgan *et al.*, 2000).

Like with DA, corticosteroids may affect brain 5-HT signaling directly and through interaction with other neurotransmitter systems (Chaouloff, 2000). Inheritable properties of the 5-HT system have also been associated with HPA-axis activity, personality and mood alterations in human and other animals. Examples are differences in MAO and polymorphisms in the 5-HT transporter gene or promoter region (Lesch *et al.*, 1996; Shih *et al.*, 1999; Fernandez *et al.*, 2003).

The interaction between different signaling systems involved in the stress response is, in fact, so complex that on occasions it appears futile to disentangle causes and consequences. Most research on neuroendocrine control of behavioral and physiological stress responses has been carried out on mammals. However, the complexity of the interaction between a single neurotransmitter, 5-HT, and stress is well illustrated by a series of studies with salmonid fish: Stress affects 5-HT metabolism and most likely also functional release (Winberg and Nilsson, 1993; Øverli *et al.*, 1998, 1999, 2001; Lepage *et al.*, 2002) and 5-HT in turn affects behavior (Winberg *et al.*, 1993, 2001) and cortisol release (Winberg *et al.*, 1997; Höglund *et al.*, 2002b; Lepage *et al.*, 2002, 2003). Cortisol also affects behavior (Øverli *et al.*, 2002b), while both stressful and rewarding behavior influence 5-HT as well as stress hormones (Winberg and Lepage, 1997; Øverli *et al.*, 1999, 2004a). Finally, there is preliminary evidence that circulating cortisol act on brain 5-HT neurons and can modify neurotransmission also in fish (Øverli *et al.*, 2003).

Thus, it is not surprising that selection for stress responsiveness is also associated with alterations in brain 5-HT activity (Øverli *et al.*, 2001, Table 1). However, at present it is not known to what degree the physiological and behavioral profiles of HR and LR trout are a result of innate differences in central signaling systems, of glucocorticoid influence on brain function, or a combination of these factors. Finally, it should be kept in mind that the differences in stress induced cortisol concentrations between HR and LR fish might arise from differences in interrenal function, rather than in central HPA-axis control (Pottinger and Carrick, 2001b). Similarly, seasonal variations in stress-induced plasma corticosteroid levels was correlated to alterations in adrenocortical cell steroidogenic function in lizards (*Sceloporus undulatus*) (Carsia and John-Alder, 2003). Thus, the possibility should be considered that differences in neurochemistry and behavior between HR and LR trout are a result of variation in interrenal influence on brain functions, rather than the opposite. However, differences between unstressed HR and LR lines also have been observed, and in these cases interrenal function are unlikely to be directly responsible.

Further experiments with HR and LR trout lines

In summary, experiments carried out on the HR and LR trout lines demonstrate a tight coupling of physiological and behavioral stress responses. The neuroendocrine control mechanisms behind this connection appear to be evolutionarily conserved, and are well illustrated by genetically selected strains of animals that display simultaneous differences in physiology and behavior. In many ways, selection models are superior to targeted gene knock-outs, since an entire suite of neuroendocrine mechanisms are selected for, instead of altering just one specific gene product. The systems that produce behavioral and neuroendocrine stress responses work in an integrated fashion, and selection models keep that integration intact.

Continuing studies on the 3rd generation HR and LR trout lines are providing evidence that the range of behavioral traits in which there are pronounced differences between the two lines far exceeds what has so far been published. For instance, a recent study has demonstrated that the extinction of a conditioned response occurs more rapidly among fish from the HR line than fish from the LR line, suggesting that the two lines differ in cognitive function as well as in behavioral characteristics (Moreira *et al.*, 2004). It is, however, not known whether this result depends on differences in memory formation, consolidation, or retrieval. This latter point is of particular interest, since some studies suggest dual effects of glucocorticoids on specific memory phases (Roosendaal, 2002). Furthermore, the results of Moreira *et al.* (2004) suggest that densities and composition of *N*-methyl-D-aspartate (NMDA) receptors are also likely to differ between the lines, in view of the important role of these receptors in excitatory neurotransmission, synaptic plasticity, and cognition in other vertebrates.

One neurotransmitter system that is also likely to play a central role in shaping behavioral profiles, but that has not been studied in the HR/LR trout model, is CRH. It is, for instance, not known whether basal or stress-induced CRH activity differs between the lines, although their behavioral and physiological profile strongly suggests such a difference. As suggested by Clements *et al.* (2003), it would also be interesting to compare the responses of these two lines to CRH treatment.

In a different venue of research, recently developed genomic tools, such as microarray technology, are being utilized in an EU program (STRESSGENES) to identify candidate genes associated with resistance to stress. Knowledge of the genes responsible for trait variability will further point out the pathways responsible for the phenotypical differences between HR and LR lines. This should provide the physiological and genetic basis for new marker-assisted selection strategies in the rapidly developing finfish aquaculture industry, as well as increased knowledge of the function and evolution of central neuroendocrine signaling systems.
