Abstract

Kernel Principal Component Analysis is a technique to perform feature extraction in a high-dimensional feature space which is nonlinearly related to the original input space. The kernel PCA formulation corresponds to an eigendecomposition of the kernel matrix: eigenvectors with large eigenvalue correspond to the principal components in the feature space. Starting from the Least Squares Support Vector Machine (LS-SVM) formulation to kernel PCA, we extend it to a generalized form with a general underlying loss function made explicit. For classical kernel PCA, the underlying loss function is $L_2$. In this generalized form, one can plug in also other loss functions. In the context of robust statistics it is known that the $L_2$ loss function is not robust because its influence function is not bounded. Therefore outliers can skew the solution from the desired one. Another issue with kernel PCA is the lack of sparseness: the principal components are dense expansions in terms of kernel functions. In this paper, we introduce robustness and sparseness into kernel component analysis by using an epsilon insensitive robust loss function. We propose two different algorithms. The first method solves a set of nonlinear equations using a sequential quadratic programming method with kernel PCA as starting points. The second method uses a simplified iterative weighting procedure that leads to solving a sequence of generalized eigenvalue problems. Simulations with toy and real-life data show improvements in terms of robustness together with a sparse representation.

Keywords: Kernel principal component analysis, Least Squares Support Vector Machines, loss function, robustness, sparseness, epsilon insensitive loss function.
I. INTRODUCTION

Principal Component Analysis (PCA) is a powerful unsupervised learning technique widely used for feature extraction, denoising and compression [1]. It is an orthogonal basis transformation where the new basis is found by an eigendecomposition of the covariance matrix $C$ of a normalized dataset. PCA constructs the rank $k$ subspace approximation to the training data that is optimal in a least squares sense, where $k < d$ and $d$ is the input dimensionality. Although PCA is a powerful technique, it cannot detect nonlinear structures in the input data [2]. Kernel PCA, as a natural nonlinear generalization of PCA, first maps the input data into some feature space $\mathcal{F}$ via a nonlinear feature map $\varphi$ induced by a kernel and then performs linear PCA on the mapped data. The projections onto the subspace spanned by the eigenvectors now lie in $\mathcal{F}$ but in many applications we need the corresponding patterns in the input space. In order to recover the extracted features or the denoised patterns we have to map from $\mathcal{F}$ back to the input space (also called the pre-image problem [3]–[6]). In [7] it was shown that kernel PCA can be derived as the dual problem to a primal optimization problem formulated in a kernel induced feature space. With this formulation the underlying loss function associated to classical kernel PCA was shown to be $L_2$. In the context of robust statistics it is known that the $L_2$ loss function is not robust because its influence function is not bounded [8], [9], hence outliers can arbitrarily deviate the solution from the desired one. Even though the approach based on influence functions was developed mainly for regression, an explicit formulation for the PCA influence function was derived in [10], showing that it is unbounded and confirming its sensitivity to outliers and therefore its non-robust nature. In [11] a statistical physics approach to PCA was studied in order to obtain robust principal components. The resulting formulation led to a bounded influence function as it was demonstrated in [12]. Another issue with kernel PCA is the lack of sparseness because the principal components are expressed in terms of a dense expansion of kernels associated with every training data point. Several approaches have been developed to introduce sparseness into kernel PCA, see e.g. [4], [13].

In this paper we derive a generalized formulation where the loss function associated to kernel PCA is explicit and can easily be changed. By incorporating an epsilon insensitive zone into a robust loss function it is possible to impose robustness and sparseness into kernel PCA. Two different algorithms are proposed. The first one solves a set of nonlinear equations using e.g. a sequential quadratic programming (SQP) method with classical kernel PCA eigenvalues/vectors as starting points. The second proposed algorithm is a simplified weighting scheme that results in solving a sequence of generalized eigenvalue problems. With this scheme, every data point in the training set has an associated weight which determines its
importance in the component calculation. We also propose a model selection method on validation data to find the kernel parameters and the number of components. This tuning method looks for parameters that maximize a criterion based on the proposed loss function. A heuristic to obtain good choices of the proposed loss function parameters is also proposed.

This paper is organized as follows: Section II describes the links between Least Squares Support Vector Machines (LS-SVMs) and kernel PCA. In Section III we propose two approaches to extend the kernel PCA formulation to other loss functions. Section IV discusses robustness and sparseness in relation to the chosen loss function. In Section V we review three pre-image algorithms that can be combined with the new method. In Section VI we propose two algorithms to find components with a general loss function. Section VII describes a model selection method. In Section VIII we report the empirical results and in Section IX we give conclusions.

II. LS-SVMs and Kernel PCA

Least squares support vector machines (LS-SVM) formulations to different problems were discussed by Suykens et al. in [14]. It emphasizes primal-dual interpretations for a class of kernel machines in terms of constrained optimization problems. LS-SVMs have been studied with respect to kernel Fisher discriminant analysis, kernel ridge regression, kernel canonical correlation analysis, kernel partial least-squares, recurrent networks, control, kernel PCA and others [7], [14]. In this Section we discuss LS-SVM formulations to kernel PCA which are relevant for the sequel of the paper.

A. Classical PCA formulation

In classical PCA formulation, one considers a given set of zero mean and normalized data \( \{x_i\}_{i=1}^N \) with \( x_i \in \mathbb{R}^d \). The objective is to find projected variables \( w^T x \) with maximal variance:

\[
\max_w \text{Var}(w^T x) \simeq \frac{1}{N} \sum_{i=1}^N (w^T x_i)^2 = w^T C w
\]

such that \( w^T w = 1 \), where \( C = (1/N) \sum_{i=1}^N x_i x_i^T \) is the sample covariance matrix. The Lagrangian for this constrained optimization problem is given by:

\[
\mathcal{L}(w; \lambda) = \frac{1}{2} w^T C w - \lambda (w^T w - 1)
\]
where \( \lambda \) is a Lagrange multiplier. From the conditions for optimality \( \partial L/\partial w = 0, \partial L/\partial \lambda = 0 \) one obtains the eigenvalue problem:

\[
Cw = \lambda w. \tag{3}
\]

The eigenvector \( w \) corresponding to the largest eigenvalue defines the direction in which the projected variables have maximal variance. Subsequent eigenvectors and eigenvalues are usually found by deflating the data matrix or by adding orthogonality constraints with respect to the previously found eigenvectors [1].

**B. LS-SVM Approach to Kernel PCA**

1) Unconstrained Formulation: Consider the following unconstrained optimization problem:

\[
\min_w J(w) = \frac{\gamma}{2N} \sum_{i=1}^{N} (w^T (\varphi(x_i) - \hat{\mu}_\varphi))^2 - \frac{1}{2} w^T w \tag{4}
\]

where \( \gamma \) is a positive regularization constant, \( \hat{\mu}_\varphi = (1/N) \sum_{j=1}^{N} \varphi(x_j) \) and \( \varphi(\cdot) : \mathbb{R}^d \rightarrow \mathbb{R}^{n_h} \) is the mapping to a high dimensional feature space \( \mathcal{F} \) of dimension \( n_h \) (which can be infinite dimensional).

**Proposition 1:** Each eigenvector \( w^* \) with corresponding eigenvalue \( \rho \) of the sample covariance matrix in the feature space \( C_\varphi = (1/N) \sum_{j=1}^{N} (\varphi(x_j) - \hat{\mu}_\varphi)(\varphi(x_j) - \hat{\mu}_\varphi)^T \) is a stationary point of \( J(w) \) given that \( \gamma = 1/\rho \). The objective function \( J(w) \) evaluated at any eigenvector \( w^* \) equals zero.

**Proof:** The optimization problem in (4) can be written as:

\[
\min_w J(w) = \frac{\gamma}{2} w^T C_\varphi w - \frac{1}{2} w^T w \rightarrow = \frac{1}{2} w^T (\gamma C_\varphi - I_n) w.
\]

Using the first-order optimality condition \( \partial J(w)/\partial w = 0 \) leads to

\[
C_\varphi w^* = \rho w^*, \tag{5}
\]

which is an eigenvalue problem of \( C_\varphi \) with \( \rho = 1/\gamma \) and corresponding eigenvector \( w^* \) such that \( (w^*)^T w^* = 1 \). The objective function becomes

\[
J(w^*) = \frac{\gamma}{2} (w^*)^T \rho w^* - \frac{1}{2} (w^*)^T w^* = (\frac{\gamma}{2} - \frac{1}{2}) (w^*)^T w^* = 0
\]

**Remark 1:** Note that solving (5) becomes intractable for high dimensional feature spaces and the size

DRAFT
of the sample covariance matrix $C_\varphi$ may become too large.

2) Constrained Formulation: Now consider the following constrained optimization problem obtained by introducing additional variables $e_i$ into (4):

$$
\min_{w,e} J_p(w,e) = \frac{\gamma}{2N} \sum_{i=1}^N e_i^2 - \frac{1}{2} w^T w
$$

such that $e_i = w^T (\varphi(x_i) - \hat{\mu}_\varphi), i = 1, ..., N.$

**Lemma 1:** Given a positive definite kernel function $K : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ with $K(x,z) = \varphi(x)^T \varphi(z)$ and a regularization constant $\gamma \in \mathbb{R}^+$, the dual problem to (6) is given by the following eigenvalue problem:

$$
\Omega_c \alpha = \lambda \alpha
$$

where $\Omega_c$ denotes the centered kernel matrix with $ij$-th entry:

$$
\Omega_{c,ij} = K(x_j, x_r) - \frac{1}{N} \sum_{r=1}^N K(x_r, x_r) + \frac{1}{N^2} \sum_{r=1}^N \sum_{s=1}^N K(x_r, x_s)
$$

and $\lambda = N/\gamma$. Assume that $\Omega_c - N(I_N/\gamma) \leq 0$ and $\gamma C_\varphi - I_N \geq 0$, then the strong duality property holds.

**Proof:** Consider the Lagrangian of the problem (6):

$$
\mathcal{L}(w,e_i; \alpha) = \frac{\gamma}{2N} \sum_{i=1}^N e_i^2 - \frac{1}{2} w^T w - \sum_{i=1}^N \alpha_i (e_i - w^T (\varphi(x_i) - \hat{\mu}_\varphi))
$$

In general the min-max inequality holds [15]:

$$
\max_\alpha \min_{w,e_i} \mathcal{L}(w,e_i; \alpha) \leq \min_{w,e_i} \max_\alpha \mathcal{L}(w,e_i; \alpha)
$$

which means that the optimal value to the dual problem is a lower bound on the optimal value to the primal problem. When (8) is fulfilled with a strict equality then the duality gap is zero and strong duality holds. Maximizing $\mathcal{L}(w,e_i; \alpha)$ with respect to $\alpha$ leads to the unconstrained optimization problem (4). Thus, the right hand side of (8) is zero at the stationary points (see Proposition 1). Minimizing the Lagrangian with respect to $e_i$ leads to the optimality condition

$$
\frac{\partial \mathcal{L}}{\partial e_i} = 0 \rightarrow e_i = \frac{N}{\gamma} \alpha_i, i = 1, \ldots, N.
$$

The Lagrangian is a concave quadratic function of $w$ therefore is unbounded below. However, the stationary point is given by the optimality condition

$$
\frac{\partial \mathcal{L}}{\partial w} = 0 \rightarrow w = \sum_{i=1}^N \alpha_i (\varphi(x_i) - \hat{\mu}_\varphi).
$$
Eliminating $w$ and $e_i$ leads to:

$$
\max_{\alpha_i} \mathcal{L}(\alpha_i) = \frac{1}{2} \sum_{i,j=1}^{N} \alpha_i \alpha_j (\varphi(x_j) - \hat{\mu}_\varphi) \mathbf{T} (\varphi(x_i) - \hat{\mu}_\varphi) - \frac{N}{2\gamma} \sum_{i=1}^{N} \alpha_i^2.
$$

By making use of the positive definite kernel function

$$
(\varphi(x_i) - \hat{\mu}_\varphi) \mathbf{T} (\varphi(x_j) - \hat{\mu}_\varphi) = K(x_i, x_j) - \frac{1}{N} \sum_{r=1}^{N} K(x_i, x_r) - \frac{1}{N} \sum_{r=1}^{N} K(x_j, x_r)
$$

$$
+ \frac{1}{N^2} \sum_{r=1}^{N} \sum_{s=1}^{N} K(x_r, x_s) = \Omega_c(x_i, x_j)
$$

one obtains the dual problem:

$$
\max_{\alpha} \mathcal{L}(\alpha) = \frac{1}{2} \alpha \mathbf{T} (\Omega_c - \frac{N}{\gamma} I_N) \alpha
$$

where $\alpha = [\alpha_1, \ldots, \alpha_N]$, $\Omega_c = M_c \Omega M_c$, $\Omega$ is the kernel matrix with $ij$-th entry $\Omega_{ij} = K(x_i, x_j)$ and $M_c = I_N - (1/N)1_N 1_N^\mathbf{T}$ is the centering matrix. Using $\partial \mathcal{L}(\alpha)/\partial \alpha = 0$ and defining $\lambda = N/\gamma$ leads to the eigenvalue problem (7). Given that $\alpha^*$ is an eigenvector of $\Omega_c$ with corresponding eigenvalue $\lambda = N/\gamma$, the dual objective function value becomes $\mathcal{L}(\alpha^*) = 1/2(N/\gamma - N/\gamma) = 0$, therefore strong duality holds.

**Remark 2:** Note that every eigenvalue/eigenvector pair of $\Omega_c$ is a stationary point of (6) with objective function value equal to zero. Therefore, the principal components can be seen as a pool of possible solutions. The problem of component selection can be solved by sorting the components in decreasing order with respect to $\lambda$ which corresponds to the variance in the $L_2$ case. This differs from classical PCA where the objective function value at the optima is the eigenvalue and reflects the amount of variance captured by the projection onto the corresponding eigenvector.

**Remark 3:** Note that changing the minimization operator to maximization in (6) leads to the same set of stationary points (7) and Remark 2 also holds.

**Remark 4:** Note that (7) corresponds to kernel PCA as proposed by Schölkopf et al. in [2], where [7] showed that a similar form of (6) is the underlying optimization problem to which kernel PCA is the dual. It is also remarkable that (7) is regularized by restricting the eigenvectors to the unit ball while regularization is explicitly present on the other hand in the primal problem in (6) through the regularization term.

**Remark 5:** Considering a bias term in (6) leads to centering the kernel matrix $\Omega$ in the feature space...
such that the mapped data have zero mean, see [7]. The bias term becomes

$$b = -\frac{1}{N}1^T_N \Omega \alpha.$$  \hspace{1cm} (13)

**Remark 6:** The projections of a datapoint $x$ onto an eigenvector (also called the score variables) become:

$$z(x) = w^T(\varphi(x) - \hat{\mu}_\varphi) = \sum_{l=1}^{N} \alpha_l \left( K(x_l, x) - \frac{1}{N} \sum_{r=1}^{N} K(x_r, x) \right) - \frac{1}{N} \sum_{r=1}^{N} K(x_r, x_l) + \frac{1}{N^2} \sum_{r=1}^{N} \sum_{s=1}^{N} K(x_r, x_s).$$  \hspace{1cm} (14)

### III. Extension to Other Loss Functions

#### A. Set of Nonlinear Equations

In (6) the kernel PCA uses the $L_2$ loss function. By extending the formulation now to a general loss function $L : \mathbb{R} \rightarrow \mathbb{R}$ and introducing a bias term $b$, the following problem can be formulated:

$$\min_{w,e_i,b} J_p(w,e_i,b) = \frac{\gamma}{2} \sum_{i=1}^{N} L(e_i) - \frac{1}{2} w^T w$$  \hspace{1cm} (15)

such that  

$$e_i = w^T \varphi(x_i) + b, \ i = 1, ..., N$$

**Lemma 2:** Given a positive definite kernel function $K : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}$ with $K(x, z) = \varphi(x)^T \varphi(z) : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}$, a differentiable loss function $L : \mathbb{R} \rightarrow \mathbb{R}$ and positive regularization constant $\gamma$, the local optimal solutions to the problem (15) can be obtained as the solution to the following set of nonlinear equations with unknowns $\alpha_i, i = 1, \ldots, N$ (dual problem) and $b$:

$$\begin{cases} 
\alpha_i - \frac{\gamma}{2} L'(\sum_{l=1}^{N} \alpha_l K(x_l, x_i) + b) = 0, \ i = 1, ..., N \\
\sum_{i=1}^{N} L'(\sum_{l=1}^{N} \alpha_l K(x_l, x_i) + b) = 0
\end{cases}$$  \hspace{1cm} (16)

**Proof:** Consider the Lagrangian of the problem (6):

$$L(w, e_i, b; \alpha) = \frac{\gamma}{2} \sum_{i=1}^{N} L(e_i) - \frac{1}{2} w^T w - \sum_{i=1}^{N} \alpha_i (e_i - w^T \varphi(x_i) - b)$$  \hspace{1cm} (17)
with Karush-Kuhn-Tucker (KKT) optimality conditions:

\[
\begin{align*}
\frac{\partial L}{\partial w} = 0 & \Rightarrow w = \sum_{i=1}^{N} \alpha_i \varphi(x_i) \\
\frac{\partial L}{\partial e_i} = 0 & \Rightarrow \alpha_i = \frac{\gamma}{2} L'(e_i), \ i = 1, \ldots, N \\
\frac{\partial L}{\partial b} = 0 & \Rightarrow \sum_{i=1}^{N} \alpha_i = 0 \\
\frac{\partial L}{\partial \alpha_i} = 0 & \Rightarrow e_i = w^T \varphi(x_i) + b, \ i = 1, \ldots, N.
\end{align*}
\]

Eliminating \(w, e_i\) leads to:

\[
\begin{align*}
\frac{\gamma}{2} L'(\sum_{l=1}^{N} \alpha_l \varphi(x_l)^T \varphi(x_l) + b) &= \alpha_i, \ i = 1, \ldots, N, \\
\sum_{i=1}^{N} L'(\sum_{l=1}^{N} \alpha_l \varphi(x_l)^T \varphi(x_l) + b) &= 0
\end{align*}
\]

and applying the definition of a positive definite kernel function gives the set of nonlinear equations (16).

\textbf{Remark 7:} Note that in general (15) is a non-convex problem, therefore the KKT optimality conditions are necessary but not sufficient.

\textbf{Remark 8:} Note that (16) leads to a different centering in the feature space, because the bias term is also affected by the loss function. This is important for robustness because the bias term is related to the estimation of the mean in the feature space as shown in the \(L_2\) case.

\textbf{Remark 9:} Note that the concept of eigenvalue and eigenvector does not exist in (16).

\textbf{Remark 10:} The score variables become

\[
z(x) = w^T \varphi(x) + b = \sum_{i=1}^{N} \alpha_i K(x_l, x) + b. \quad (18)
\]

\textbf{Remark 11:} Consider the minimization of the \(L_2\) loss of the residuals:

\[
U^* = \arg\min_U \sum_{i=1}^{N} r_i^2 
\]

where \(r_i = ||\varphi(x_i) - P_U \varphi(x_i)||_2\), \(U\) denotes an orthogonal subspace and \(P_U \varphi(x_i)\) denotes the projection of the \(i\)-th mapped datapoint onto \(U\). Since \(P_U \varphi(x_i)\) is an orthogonal projection, one can write

\[
||\varphi(x_i) - P_U \varphi(x_i)||^2_2 = ||\varphi(x_i)||^2_2 - ||P_U \varphi(x_i)||^2_2
\]
which leads to

\[ U^* = \arg\max_U \sum_{i=1}^{N} ||P_U \varphi(x_i)||_2^2. \]

This shows that minimizing the sum of the \( L_2 \) loss of the residuals is equivalent to maximizing the sum of the \( L_2 \) loss of the projections. However, in the case of a general loss function \( L \), this equivalence no longer holds. Hence, a general loss function can be applied to the projections \( e \) but the loss function applied to the primal vector \( w \) should be \( L_2 \) in order to exploit the equivalence between a dot product in the feature space and a kernel function evaluation.

B. A Simplified Weighting scheme

Another approach to extend kernel PCA to general loss functions is to consider a loss function of the form \( L(e_i) = v_i^{(k)} e_i^2 \) where \( v_i^{(k)} \), \( i = 1, \ldots, N \) are user-defined weights and \( k \) is the iteration step. A two-step weighting scheme was proposed in [16] to impose robustness in LS-SVM regression. In the first step, an unweighted LS-SVM is calculated. The second stage consists of associating weighting values to the error variables obtained in the first step. This scheme can also be employed in kernel PCA as a simplified technique to obtain robust and sparse solutions. Introducing weighting factors \( v_i^{(k)} \) in the formulation leads to the following primal optimization problem:

\[
\min_{w,e_i} J_p(w, e_i) = \frac{1}{2} \sum_{i=1}^{N} v_i^{(k)} e_i^2 - \frac{1}{2} w^T w
\]

such that \( e_i = w^T (\varphi(x_i) - \hat{\mu}_\varphi), \ i = 1, \ldots, N. \)

A simple method is to make a two-step approach. In general it can be more steps as well. A precise convergence analysis is needed in that case. However, here we are interested in a simple way to cheaply incorporate robustness and sparseness to kernel PCA. In the first step, an unweighted kernel PCA solution is obtained, \( (v_i^{(1)} = 1, i = 1, \ldots, N) \). Then the weights are calculated in the second step in such a way that \( v_i^{(2)} e_i^2 = L(e_i) \). The advantage of this approach is that one extends kernel PCA to general loss functions by solving a sequence of generalized eigenvalue problems which can be solved efficiently, while in (16) one needs to solve a set of nonlinear equations which may lead to local optima and slow convergence.

The first weighted principal component is the solution to (20). The second weighted component is the solution to (20) with an additional constraint. This constraint imposes orthogonality with respect to the score variables associated to the previously found weighted component. For the third weighted component, two constraints are added to ensure orthogonality with respect to the score variables for
the second and first weighted principal components. This iterative process is repeated until all required weighted components are obtained. Hence, the \( m \)-th weighted principal component is the solution to the following primal problem with a number of \( m - 1 \) orthogonality constraints:

\[
\min_{w,e_i} J_p(w,e_i) = \frac{1}{2} \sum_{i=1}^{N} v_i^{(k)} e_i^2 - \frac{1}{2} w^T w
\]

such that

\[
\begin{align*}
  e_i &= w^T (\varphi(x_i) - \hat{\mu}_\varphi), \; i = 1, \ldots, N \\
  \sum_{i=1}^{N} e_i e_i^{(1)} &= 0 \\
  \sum_{i=1}^{N} e_i e_i^{(2)} &= 0 \\
  \vdots \\
  \sum_{i=1}^{N} e_i e_i^{(m-1)} &= 0
\end{align*}
\]

where \( k = 0, \ldots, N_{\text{iter}} \) is the iteration step, \( e_i^{(l)} \), \( l = 1, \ldots, m - 1 \) are the score variables corresponding to the \( l \)-th previously found weighted principal component, which are assumed to be given.

**Lemma 3:** Given a positive definite kernel function \( K : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R} \) with \( K(x,z) = \varphi(x)^T \varphi(z) \), score variables \( e_i^{(1)}, e_i^{(2)}, \ldots, e_i^{(m-1)} \in \mathbb{R}, \; i = 1, \ldots, N \) and positive weighting factors \( v_i^{(k)} \in \mathbb{R}^+, \; i = 1, \ldots, N \), the solution to the problem (21) is given by the following generalized eigenvalue problem:

\[
\begin{bmatrix}
  \Omega_e^V \\
  0_{N \times (m-1)}^T \\
  0_{(m-1) \times (m-1)}^T
\end{bmatrix}
\begin{bmatrix}
  \alpha \\
  \beta
\end{bmatrix}
= \lambda
\begin{bmatrix}
  I_N \\
  E^T \\
  D
\end{bmatrix}
\begin{bmatrix}
  \alpha \\
  \beta
\end{bmatrix}
\]

(22)

where \( V^{(k)} = \text{diag}(v_1^{(k)}, \ldots, v_N^{(k)}) \), \( \Omega_e^V = V^{(k)} \Omega_e \), \( 0_{p \times q} \) is the \( p \times q \) zero matrix, \( \alpha = [\alpha_1; \ldots; \alpha_N] \), \( \beta = [\beta_1; \beta_2; \ldots; \beta_{m-1}] \), \( \lambda = 1/\gamma \), \( I_N \) is the \( N \times N \) identity matrix and \( E, D \) are defined as follows:

\[
E = \begin{bmatrix}
  e_1^{(1)} & e_2^{(1)} & \cdots & e_N^{(1)} \\
  e_1^{(2)} & e_2^{(2)} & \cdots & e_N^{(2)} \\
  \vdots & \vdots & \ddots & \vdots \\
  e_1^{(m-1)} & e_2^{(m-1)} & \cdots & e_N^{(m-1)}
\end{bmatrix}
\]

\[
D = \begin{bmatrix}
  \sum_i (e_i^{(1)})^2 \\
  \sum_i (e_i^{(2)})^2 \\
  \vdots \\
  \sum_i (e_i^{(m-1)})^2
\end{bmatrix}
\]
Proof: Consider the Lagrangian of the problem (21):

\[
\mathcal{L}(w, e; \alpha_i, \beta_j) = \gamma \frac{1}{2} \sum_{i=1}^{N} v_i^{(k)} e_i^2 - \frac{1}{2} w^T w - \sum_{i=1}^{N} \alpha_i (e_i - w^T (\varphi(x_i) - \hat{\mu}_\varphi))
- \beta_1 \sum_{i=1}^{N} e_i e^{(1)}_i - \beta_2 \sum_{i=1}^{N} e_i e^{(2)}_i - \ldots - \beta_{i-1} \sum_{i=1}^{N} e_i e^{(m-1)}_i
\]

(23)

with conditions for optimality:

\[
\frac{\partial \mathcal{L}}{\partial w} = 0 \rightarrow w = \sum_{i=1}^{N} \alpha_i (\varphi(x_i) - \hat{\mu}_\varphi)
\]

(24)

\[
\frac{\partial \mathcal{L}}{\partial e_i} = 0 \rightarrow e_i = \frac{1}{\gamma v_i^{(k)}} (\alpha_i + \beta_1 e^{(1)}_i + \beta_2 e^{(2)}_i + \ldots + \beta_{i-1} e^{(m-1)}_i), \ i = 1, \ldots, N
\]

(25)

\[
\frac{\partial \mathcal{L}}{\partial \alpha_i} = 0 \rightarrow e_i = w^T (\varphi(x_i) - \hat{\mu}_\varphi), \ i = 1, \ldots, N
\]

(26)

\[
\frac{\partial \mathcal{L}}{\partial \beta_1} = 0 \rightarrow \sum_{i=1}^{N} e_i e^{(1)}_i = 0
\]

\[
\frac{\partial \mathcal{L}}{\partial \beta_2} = 0 \rightarrow \sum_{i=1}^{N} e_i e^{(2)}_i = 0
\]

\[
\vdots
\]

\[
\frac{\partial \mathcal{L}}{\partial \beta_{i-1}} = 0 \rightarrow \sum_{i=1}^{N} e_i e^{(m-1)}_i = 0.
\]

Using (24), (25) and (26) leads to:

\[
\frac{1}{\gamma} (\alpha_i + \beta_1 e^{(1)}_i + \beta_2 e^{(2)}_i + \ldots + \beta_{m-1} e^{(m-1)}_i) = v_i \sum_{j=1}^{N} \alpha_j (\varphi(x_j) - \hat{\mu}_\varphi)^T (\varphi(x_i) - \hat{\mu}_\varphi), \ i = 1, \ldots, N.
\]

Applying the property ofMercel kernels:

\[
\frac{1}{\gamma} (\alpha_i + \beta_1 e^{(1)}_i + \beta_2 e^{(2)}_i + \ldots + \beta_{m-1} e^{(m-1)}_i) = v_i^{(k)} \sum_{j=1}^{N} \alpha_j \Omega_c(x_j, x_i), \ i = 1, \ldots, N.
\]

(27)
Substituting (25) into the orthogonality constraints leads to the following set of equations:

\[
\begin{align*}
\sum_{j=1}^{N} \frac{\alpha_j e^{(1)}_j}{v_j^{(k)}} + \beta_1 \sum_{j=1}^{N} \frac{(e^{(1)}_j)^2}{v_j^{(k)}} + \beta_2 \sum_{j=1}^{N} \frac{e^{(1)}_j e^{(2)}_j}{v_j^{(k)}} + \ldots + \beta_{m-1} \sum_{j=1}^{N} \frac{e^{(1)}_j e^{(m-1)}_j}{v_j^{(k)}} &= 0 \\
\sum_{j=1}^{N} \frac{\alpha_j e^{(2)}_j}{v_j^{(k)}} + \beta_1 \sum_{j=1}^{N} \frac{e^{(1)}_j e^{(2)}_j}{v_j^{(k)}} + \beta_2 \sum_{j=1}^{N} \frac{(e^{(2)}_j)^2}{v_j^{(k)}} + \ldots + \beta_{m-1} \sum_{j=1}^{N} \frac{e^{(1)}_j e^{(m-1)}_j}{v_j^{(k)}} &= 0 \\
\vdots \\
\sum_{j=1}^{N} \frac{\alpha_j e^{(m-1)}_j}{v_j^{(k)}} + \beta_1 \sum_{j=1}^{N} \frac{e^{(1)}_j e^{(m-1)}_j}{v_j^{(k)}} + \beta_2 \sum_{j=1}^{N} \frac{e^{(2)}_j e^{(m-1)}_j}{v_j^{(k)}} + \ldots + \beta_{m-1} \sum_{j=1}^{N} \frac{(e^{(m-1)}_j)^2}{v_j^{(k)}} &= 0.
\end{align*}
\]

The sets of equations (27) and (28) give the generalized eigenvalue problem (22). □

**Lemma 4:** The matrix \( M = \begin{bmatrix} \Omega_c^V & 0_{N \times (m-1)} \\ 0_{N \times (m-1)}^T & 0_{(m-1) \times (m-1)} \end{bmatrix} \) is positive semidefinite.

**Proof:** The matrix \( \Omega_c^V \) is the product of two positive definite matrices \( V^{(k)} \) and \( \Omega_c \). Thus, by Theorem 7.6.3 of [17], \( \Omega_c^V \) is also positive definite.

The eigendecomposition of \( M \):

\[
\begin{bmatrix} \Omega_c^V & 0_{N \times (m-1)} \\ 0_{N \times (m-1)}^T & 0_{(m-1) \times (m-1)} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \lambda \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}
\]

is equal to

\[
\begin{bmatrix} \Omega_c^V x_1 \\ 0_{(m-1) \times 1} \end{bmatrix} = \lambda \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}.
\]

Hence, the non-zero eigenvalues of \( M \) are identical to the eigenvalues of \( \Omega_c^V \). □

**Corollary 1:** The generalized eigenvalue problem in (22) has real eigenvalues.

**Proof:** Let (22) be written as \( Mp = \lambda Bp \):

\[
B = \begin{bmatrix} I_N & E \\ E^T & D \end{bmatrix}, \quad p = \begin{bmatrix} \alpha \\ \beta \end{bmatrix}
\]

with \( p \in \mathbb{C}^{N+i-1} \).

Then, premultiplying by the complex conjugate \( p^* \) leads to

\[
p^* M p = \lambda p^* B p
\]
the generalized eigenvalues become:

\[ \lambda = \frac{p^*Mp}{p^*Bp}. \]

Since \( M \) is positive semidefinite (Corollary 4), and \( B \) is Hermitian, the generalized eigenvalues become the ratio of two real numbers.

**Remark 12:** Note that \( \lambda \) in (22) can be negative. However, only positive \( \lambda \) values are considered.

### IV. Robustness and Sparseness

#### A. Robustness in kernel PCA

It is known that classical PCA is heavily influenced by outlying observations. A single outlier can by itself determine an entire component. The subspace approximation to the training data that PCA constructs is optimal only in a least-squares sense [1]. A small deviation from the assumptions produces a gross error in the principal component estimation. Although several approaches to robustify PCA have been developed [11], [18], [19], [20], [21], that is not the case for kernel PCA.

In this Section, we tackle the robustness problem in kernel PCA using the approach based on influence functions introduced by Hampel *et al.* in [22]. However, an explicit form of the influence function is not given.

Let \( T_N \) be a target statistic based on the training data \( \{x_i\}_{i=1}^N \) assuming that \( T_N \) can be expressed as a functional, say \( T(\bar{F}_N) \), where \( \bar{F}_N \) indicates the empirical distribution function of the data. The influence function of \( T(\bar{F}_N) \) against an outlier \( \xi \) is defined as:

\[
IF(\xi; \bar{F}_N, T) = \lim_{t \to 0} \frac{T[(1-t)\bar{F}_N + t\delta_\xi] - T(\bar{F}_N)}{t},
\]

where \( \delta_\xi \) is the pointmass 1 distribution at \( \xi \).

If the influence function is bounded, then the influence of the functional \( T(\bar{F}_N) \) by any \( \xi \) should have a reduced effect.

The \( i \)-th principal component \( \alpha^{(i)} \) can be expressed as a functional \( \alpha^{(i)}(\bar{F}_N) \) and according to [10], [1], [12] its influence function becomes:

\[
IF(\xi; \bar{F}_N, \alpha^{(i)}) = -\beta_1(\xi) \sum_{j \neq i}^d \beta_j(\xi)(\lambda_j - \lambda_i)^{-1} \alpha^{(j)}
\]

(30)

where \( \beta_j(\xi) = (\alpha^{(j)})^T(\xi - \hat{\mu}) \), \( \lambda_j \) is the \( j \)-th eigenvalue, \( \hat{\mu} \) is the sample mean of the data and \( \alpha^{(j)} \) is the \( j \)-th principal component. Note that (30) depends of all the components and is unbounded which confirms the non-robust nature of PCA.
For *M-estimators* [8], the influence function of the functional $T(\bar{F}_N)$ is defined as:

$$IF(\xi; \bar{F}_N, T) = \frac{L'(\xi)}{\int L'(\xi) d\bar{F}_N}.$$  \hspace{1cm} (31)

In other words, the influence function of an *M-estimator* is proportional to the first derivative of the loss function (also called the score function). Several loss functions with bounded score functions have been proposed. Well-known examples are the Huber, Hampel, Welsch and Tukey loss functions. Kernel PCA has an underlying $L_2$ loss function with an unbounded score function (Fig. 1). Hence, kernel PCA is not robust against outlying data points. Note also that kernel PCA is linear PCA in a kernel-induced feature space, therefore outliers in the feature space have a large influence. Christmann *et al.* showed in [23] that the kernel and the score function should be bounded in convex risk minimization methods to achieve robustness.

**B. Sparseness**

As can be seen in (14), the score variables are expressed in terms of kernel expansions in which every training point contributes. These expansions are typically dense (non-sparse). Different methods have been proposed to overcome the lack of sparseness in kernel PCA. Smola *et al.* in [13] proposed a sparse version employing an $L_1$ penalty in the expansion coefficients. Schölkopf *et al.* in [4] introduced a compact representation for the expansions.

Because the loss function is explicit in our formulation, we can introduce an epsilon insensitive zone into the robust loss function and achieve sparseness and robustness at the same time due to the conditions for optimality in (18). This epsilon insensitive zone was introduced by Vapnik in to impose sparseness in support vector regression. We propose a robust loss function with bounded influence function and tunable parameters $\epsilon$ and $h$ for sparseness and robustness respectively. This loss function is a combination of the Huber loss and the epsilon insensitive loss function for support vector regression introduced by Vapnik in [24]. The proposed loss function (Fig. 1) is defined as:

$$L(e) = \begin{cases} 
0 & \text{if } |e| \leq \epsilon \\
\epsilon^2 - 2|e| + \epsilon^2 & \text{if } \epsilon < |e| < h \\
2(h - \epsilon)|e| - h^2 + \epsilon^2 & \text{if } |e| \geq h.
\end{cases}$$  \hspace{1cm} (32)

with $h > \epsilon$. Its score function becomes:
$\psi(e) = L'(e) = \begin{cases} 
0 & \text{if } |e| \leq \epsilon \\
2\text{sign}(e)(|e| - \epsilon) & \text{if } \epsilon < |e| < h \\
2\text{sign}(e)(h - \epsilon) & \text{if } |e| \geq h.
\end{cases}$  \hspace{1cm} (33)

Taking an epsilon zone in the loss function leads to sparseness because of the conditions for optimality (18). Note that setting $\epsilon$ to zero leads to the Huber loss function and $\epsilon > 0, h \rightarrow \epsilon$ approaches to the Vapnik epsilon insensitive loss function.

V. THE PRE-IMAGE PROBLEM

The projections onto the subspace spanned by the principal components lie in some feature space $\mathcal{F}$ but in most applications of kernel PCA we are interested in a reconstruction in the input space rather than in $\mathcal{F}$. This mapping from the feature space back to the input space is called the pre-image problem. In this Section we summarize three pre-image algorithms that will be used in the sequel.

- **Pre-image algorithm 1:**

An iterative nonlinear optimization method is proposed in [3] for Gaussian kernels, but it can suffer from numerical instabilities and local minima. Given a test point $x$ we want to recover $\hat{x}$ for which $\varphi(\hat{x}) \approx P_{N_c}\varphi(x)$, where $P_{N_c}\varphi(x)$ is the projection of $\varphi(x)$ onto the subspace spanned by the first $N_c$ principal components. For Gaussian kernels, the approximate pre-image $\hat{x}$ can be computed using the following iteration [3]:

$$
\hat{x}^{(t)} = \frac{\sum_{i=1}^{N_c} \eta_i \exp(-\|\hat{x}^{(t-1)} - x_i\|^2/\sigma^2)x_i}{\sum_{i=1}^{N_c} \eta_i \exp(-\|\hat{x}^{(t-1)} - x_i\|^2/\sigma^2)}
$$

(34)

where $\eta_i = \sum_{j=1}^{N_c} \beta_j u^{(j)}_i$, $\beta_j$ is the projection of $\varphi(x)$ onto the $j$-th component $u^{(j)}$ and $t$ is the iteration step.

- **Pre-image algorithm 2:**

Another approach is proposed in [6]. It is a modified version of (34) to remove iteratively the influence of outliers. Let $l_j^{(t)}$ be the certainty of $x^{(j)}$, where $x^{(j)}$ denotes the $j$-th coordinate of the test point $x$. This certainty is calculated using the difference between $x^{(j)}$ and the corresponding reconstruction $\hat{x}^{(t-1)}_{(j)}$ as:

$$
l_j^{(t)} = \exp(-(x^{(j)} - \hat{x}^{(t-1)}_{(j)})^2/(2\sigma_j^2)), \; j = 1, \ldots, d.
$$

(35)

The parameter $\sigma_j$ is the standard deviation of the differences and is estimated using robust estimation
\[ \sigma_j = 1.4826(1 + 5/(N - 1)) \text{median}_i \sqrt{\varepsilon_{ij}^2} \]  

(36)

where \( \varepsilon_{ij}^2 \) is the squared error between the \( j \)-th dimension of the \( i \)-th data point and its reconstruction. The approximate pre-image \( \hat{x} \) can be computed using the following iteration [6]:

\[
\hat{x}(t) = \frac{\sum_{i=1}^{N} \eta_i \exp(-\|g(t) - x_i\|^2/\sigma^2)x_i}{\sum_{i=1}^{N} \eta_i \exp(-\|g(t) - x_i\|^2/\sigma^2)}
\]

(37)

where \( g(t) \) is given by:

\[
g(t) = L(t)x + (I_d - L(t))\hat{x}(t-1),
\]

(38)

for \( t > 0 \). The matrix \( I_d \) is the \( d \times d \) identity matrix, \( d \) is the dimensionality of the input vectors, \( L(t) \) is a \( d \times d \) matrix defined as \( L(t) = \text{diag}(l_1(t), \ldots, l_d(t)) \).

• Pre-image algorithm 3:

A newer approach is proposed in [5]. This method is non-iterative, involves only linear algebra and uses the distances between the projection \( P_{N_c} \varphi(x) \) and its nearest neighbors. The method can be summarized as follows: given the \( N_n \) neighbors \( \{x_1, \ldots, x_{N_n}\} \) and \( q = [q_1, \ldots, q_{N_n}]^T \) where \( q_l \) is the input space distance between \( P_{N_c} \varphi(x) \) and \( x_l, l = 1, \ldots, N_n \), first construct the matrix \( \tilde{X} = [x_1, x_2, \ldots, x_{N_n}] \) and compute its singular value decomposition (SVD):

\[
\tilde{X}M_c = GR
\]

(39)

where \( M_c \) is the centering matrix, \( G \) is the matrix of left singular vectors, \( R = \Lambda H^T = [r_1, \ldots, r_{N_n}] \), \( \Lambda \) is the diagonal matrix of singular values, \( H \) is the matrix of right singular vectors and \( r_j \) is the projection of \( x_j \) onto \( G \), \( j = 1, \ldots, N_n \). The approximate pre-image can be obtained as:

\[
\hat{r} = -\frac{1}{2}\Lambda^{-1}H^T(q - q_0)
\]

(40)

where \( q_0 = [||r_1||^2, \ldots, ||r_{N_n}||^2]^T \). Transforming back to the original coordinate system in the input space leads to:

\[
\hat{x} = G\hat{r} + \bar{x}
\]

(41)

where \( \bar{x} = \frac{1}{N_n} \sum_{j=1}^{N_n} x_j \).
VI. ALGORITHMS

We propose two algorithms to obtain the components with the Huber epsilon-insensitive loss function. The first algorithm solves (16) using a sequential quadratic programming (SQP) approach [25] and smooth approximation of $L'(e)$. The second algorithm corresponds to an implementation of the weighted scheme (22).

A. Sequential Quadratic Programming Algorithm

The Huber epsilon-insensitive influence function $L'(e)$ is not differentiable at $|e| = \epsilon$ and $|e| = h$ therefore to use a gradient-based approach such as SQP, a smooth approximation $L_s'(e)$ to $L'(e)$ is taken:

$$L_s'(e) = \begin{cases} 
\frac{2}{s} \log \left(1 + \exp\left((s(e + h))\right)\right) - 2(h - \epsilon) & \text{if } e \leq \frac{h-\epsilon}{2} - \epsilon \\
\frac{2}{s} \log \left(\frac{1+\exp\left(-s\left(e-\epsilon\right)\right)}{1+\exp\left(-s\left(e+\epsilon\right)\right)}\right) & \text{if } \frac{h-\epsilon}{2} - \epsilon < |e| < \frac{h-\epsilon}{2} + \epsilon \\
-\frac{2}{s} \log \left(1 + \exp\left(-s\left(e - h\right)\right)\right) + 2(h - \epsilon) & \text{if } e \geq \frac{h-\epsilon}{2} + \epsilon 
\end{cases} \quad (42)$$

where $s$ is a constant that controls the smoothness of the approximation. Figure 2 shows $L_s'(e)$ and $L'(e)$ for $\epsilon = 2, h = 5, s = 20$.

Replacing $L'(\cdot)$ by $L_s'(\cdot)$ in (16) leads to:

$$f(\lambda, \alpha, b) = \left[ \frac{\lambda \alpha - \frac{1}{2} \tilde{L}_s'(z(\alpha, b))}{1^T N \tilde{L}_s'(z(\alpha, b))} \right] = 0 \quad (43)$$

where $f : \mathbb{R}^+ \times \mathbb{R}^N \times \mathbb{R} \rightarrow \mathbb{R}^{N+1}$, $\lambda = 1/\gamma$, $z(\alpha, b) = [z_1(\alpha, b); z_2(\alpha, b); \ldots; z_N(\alpha, b)]$, $\alpha = [\alpha_1; \alpha_2; \ldots; \alpha_N]$, $z_i(\alpha, b) = \Omega^{(i)} \alpha + b_1 N$, $\Omega^{(i)}$ denotes the $i$-th row of the kernel matrix $\Omega$ and

$$\tilde{L}_s'(z(\alpha, b)) = [L_s'(z_1(\alpha, b)); \ldots; L_s'(z_N(\alpha, b))].$$

The set of nonlinear equations (43) is usually solved via minimization of a sum of squares of the residuals. We impose two additional constraints $\alpha^T \alpha \geq 1$ and $\lambda \geq c$ where $c$ is a small positive constant (e.g. $c = 10^{-6}$). The first constraint prevents the trivial solution $\alpha = 0$ and non-interesting solutions with small norm causing the score variables $z_i(\alpha, b)$ to lie in the range $-h < |z_i(\alpha, b)| < h$, $i = 1, \ldots, N$, therefore avoiding the bounded zone $|z_i(\alpha, b)| \geq h$ of the score function. The proposed
nonlinear optimization problem is the following:

\[
\min_{\lambda, \alpha, b} \quad g(\lambda, \alpha, b) = f(\lambda, \alpha, b)^T f(\lambda, \alpha, b) \tag{44}
\]

such that

\[
\begin{align*}
\alpha^T \alpha &\geq 1 \\
\lambda &\geq c
\end{align*}
\]

where

\[
g(\lambda, \alpha, b) = \lambda^2 \alpha^T \alpha - \lambda \alpha^T \tilde{L}_s(z(\alpha, b)) + \frac{1}{4} (\tilde{L}_s(z(\alpha, b)) - \tilde{L}_s(z(\alpha, b)))^T \tilde{L}_s(z(\alpha, b)) + \left(1_N^T \tilde{L}_s(z(\alpha, b))\right)^2. \tag{45}
\]

All \(N + 1\) equations have to be satisfied at the local solution \((\lambda^*, \alpha^*, b^*)\) rather than just minimizing the sum of the squares of the equations. This means that the value of \(g(\lambda^*, \alpha^*, b^*)\) should be zero in order to \((\lambda^*, \alpha^*, b^*)\) to be a solution to the problem (43). In the same fashion as in the weighting scheme, additional constraints can be added to impose orthogonality with previously found components. Note that sparseness is achieved component-wise due to \(\alpha_i = \frac{\gamma}{2} L'(e_i)\) which is one of the optimality conditions (18). Therefore, each component vector may have a different number of zero \(\alpha_i\) values.

An SQP method approximates in every iteration the constrained optimization problem (44) as a quadratic programming problem of the form:

\[
\min_d \quad \frac{1}{2} d^T H^{(k)} d + \nabla g(\theta^{(k)})^T d \tag{46}
\]

such that

\[
\begin{align*}
\nabla c_1(\theta^{(k)})^T d + c_1(\theta^{(k)}) &\geq 0 \\
\nabla c_2(\theta^{(k)})^T d + c_2(\theta^{(k)}) &\geq 0
\end{align*} \tag{47}
\]

where \(k\) denotes the iteration step, \(H\) is the Hessian matrix (or an approximation to it) of the Lagrangian of (44), \(\theta = [\lambda; \alpha; b]\) is the vector of parameters, \(c_1(\theta) = \alpha^T \alpha - 1\) is the first constraint, \(c_2(\theta) = \lambda - c\) is the second constraint, \(g(\theta) = g(\lambda; \alpha; b)\) and the gradient \(\nabla g(\theta) \in \mathbb{R}^{N+2}\) is defined as:

\[
\nabla g(\theta) = \nabla g(\lambda, \alpha, b) = \begin{bmatrix}
\nabla_\lambda g(\lambda, \alpha, b) \\
\nabla_\alpha g(\lambda, \alpha, b) \\
\nabla_b g(\lambda, \alpha, b)
\end{bmatrix} \tag{48}
\]
where
\[
\nabla_{\lambda} g(\lambda, \alpha, b) = 2\lambda \alpha^T - \alpha^T \tilde{L}'_s(z(\alpha, b))
\]
\[
\nabla_{\alpha} g(\lambda, \alpha, b) = 2\lambda^2 - \lambda \left( \Omega \text{diag}\left( \tilde{L}''_s(z(\alpha, b)) \right) \alpha + \tilde{L}'_s(z(\alpha, b)) \right)
\]
\[
+ \frac{1}{2} \Omega \text{diag}\left( \tilde{L}''_s(z(\alpha, b)) \right) \tilde{L}'_s(z(\alpha, b)) + 2r_1 \Omega \tilde{L}'_s(z(\alpha, b)) + 2r_1 r_2
\]
\[
\nabla_{b} g(\lambda, \alpha, b) = -\lambda \alpha^T \tilde{L}'_s(z(\alpha, b)) + \frac{1}{2} \left( \tilde{L}'_s(z(\alpha, b)) \right)^T \tilde{L}'_s(z(\alpha, b)) + 2r_1 \]
\[
r_1 = 1^T_N \tilde{L}'_s(z(\alpha, b)), r_2 = 1^T_N \tilde{L}''_s(z(\alpha, b)).
\]
The solution vector \(d^{(k)}\) to the QP subproblem (46) can then be used to form a new iterate:
\[
\theta^{(k+1)} = \theta^{(k)} + \mu^{(k)} d^{(k)}
\]

(50)

where \(\mu^{(k)}\) is the step length parameter of the line search and can be obtained using a merit function.

A critical issue in nonlinear optimization is the selection of good starting points. In the proposed SQP approach, kernel PCA eigenvectors and eigenvalues are used as initial values for the nonlinear solver. Therefore, we are considering only the first local solution obtained through the proposed initialization.

Given a set of \(N d\)-dimensional data points \(X = \{x_1, \ldots, x_N\}\), the algorithm gives a set of \(N_c\) component vectors \(A = \{\alpha^{(1)}\ast, \ldots, \alpha^{(N_c)}\ast\}\) as follows:

**Algorithm 1** SQP Approach

1: Set the kernel parameters and the loss function parameters \(\epsilon, h\).
2: Perform an eigendecomposition of the non-centered kernel matrix to obtain initial eigenvalues \(\{\lambda_1, \ldots, \lambda_N\}\) and initial eigenvectors \(\{\alpha^{(1)}, \ldots, \alpha^{(N)}\}\).
3: for \(l = 1\) to \(N_c\) do
4: Obtain the initial values for the bias term \(b_l = (1/N)1^T_N \chi \alpha^{(l)}\)
5: Solve the SQP problem (46), (50) with initial values \(\lambda_l, \alpha^{(l)}\) and \(b_l\) to obtain the solutions \(\lambda_l^\ast, \alpha^{(l)}\ast\) and \(b_l^\ast\)
6: end for
7: Sort the solutions according to the value of \(\lambda_l^\ast\) in decreasing order.
8: Normalize the components \(\alpha^{(l)}\ast \leftarrow \alpha^{(l)}\ast / ||\alpha^{(l)}\ast||_2, l = 1, \ldots, N_c\)

**B. Weighted Algorithm**

The second algorithm is an implementation of the iterative weighting scheme (21). Given \(X\), and the number of iterations \(N_{iter}\), the algorithm (2) gives a set of \(N_c\) components \(\{\alpha^{(1)}, \ldots, \alpha^{(N_c)}\}\), where \(N_r \leq N\). In general, empirical results suggest that only one iteration \((N_{iter} = 1)\) is sufficient to obtain good results. Sparseness is achieved in step 4 by removing datapoints from the training set for which the corresponding weight is equal to zero across the components. The computational complexity
Algorithm 2 Weighted Kernel PCA

1: Set the kernel parameters, the loss function parameters \( \epsilon, h \) and the number of principal components \( N_c \) to be extracted.

2: Compute the unweighted score variables \( e_{i}^{(l)}, i = 1, \ldots, N, l = 1, \ldots, N_c \) associated to the first \( N_c \) principal components using classical kernel PCA.

3: Compute the weights \( v_i^{(l)} \) such that \( v_i^{(l)}(e_i^{(l)})^2 = L(e_i^{(l)}) \).

4: Remove from the training dataset the datapoints whose corresponding weight \( v_i^{(l)} \) equals to zero in every component. The new dataset has \( N_r \) datapoints.

5: Compute the unweighted score variables \( e_{i}^{(l)}, l = 1, \ldots, N_c \) of the reduced dataset using classical kernel PCA.

6: for \( k = 1 \) to \( N_{\text{iter}} \) do

7: Recompute the weights \( v_i^{(l)} \) such that \( v_i^{(l)}(e_i^{(l)})^2 = L(e_i^{(l)}) \) with \( \epsilon = 0 \).

8: Find the first weighted principal component \( \alpha^{(1)} \) which is the solution associated to the largest eigenvalue in \( V\Omega_c \alpha = \lambda \alpha \), with \( V = \text{diag}(v_1, \ldots, v_{N_r}) \).

9: Recompute \( e_i^{(l)} \) using \( \alpha^{(1)} \).

10: for \( l = 2 \) to \( N_c \) do

11: Recompute the weights \( v_i^{(l)} \) such that \( v_i^{(l)}(e_i^{(l)})^2 = L(e_i^{(l)}) \) with \( \epsilon = 0 \)

12: Find the \( l \)-th weighted principal component \( \alpha^{(l)} \) which is the solution associated to the largest eigenvalue in \( (22) \).

13: Recompute \( e_i^{(l)} \) using \( \alpha^{(l)} \).

14: end for

15: end for

of this algorithm is \( O(N_{\text{iter}}N_c(\xi N + N_c)) \) compared with \( O(\xi N) \) for classical kernel PCA using the Lanczos method for the largest \( N_c \) components. The factor \( \xi \) is the maximum number of matrix-vector computations required and depends of the eigengap \( \lambda_{N_c+1} - \lambda_{N_c} \) [26], [27].

VII. MODEL SELECTION

Model selection is a central issue in unsupervised learning techniques such as kernel PCA. In supervised learning one can rely on many methods (such as validation set, crossvalidation, generalization bounds, etc.) for model selection. However, one often cannot apply such criteria in unsupervised learning due to the lack of an underlying objective function to the method. In kernel PCA, the parameters that define the model are the number of principal components \( N_c \) to be extracted and the kernel parameters (e.g. \( \sigma^2 \) for the RBF kernel). These parameters are typically chosen in a trial-and-error fashion. In the proposed approaches, model selection in a learning framework can be done naturally on the basis of the explicit constrained optimization formulation. We propose the following model selection criterion:

\[
\max_{N_c, \sigma^2} \sum_{l=1}^{N_c} \sum_{j=1}^{N_{\text{val}}} L(\tilde{e}_j^{(l)}) \tag{51}
\]

where \( \tilde{e}_j^{(l)} = w^T \varphi(x_j^{\text{val}}) + b_l = \sum_{i=1}^{N_c} \alpha_i^{(l)} K(x_i, x_j^{\text{val}}) + b_l \) denotes the \( j \)-th validation data point, \( \alpha_i^{(l)} \) is the \( l \)-th component and \( b_l \) is the bias term for the \( l \)-th component, \( l = 1, \ldots, N_c \).
The values of $\epsilon$ (sparseness) and $h$ (robustness) are problem-dependent and can be obtained heuristically from the empirical distribution of the score variables such that a given amount of the score values lie within the epsilon zone of the loss function. In the same way, $h$ can be set such that a given percentage of the score values lie within the range $-h < \epsilon < h$. Figure 3 shows the proposed heuristic.

VIII. EMPIRICAL RESULTS

In this section, some experimental results are presented to illustrate the effectiveness of the proposed approaches. We used the MATLAB function `fmincon` to solve (46). This function is a SQP solver with a quasi-Newton approximation of the Hessian of the Lagrangian using the Broyden-Fletcher-Goldfarb-Shanno (BFGS) method. The step length is calculated with line search and the merit function described in [28]. We performed denoising experiments and feature extraction simulations which corresponds to most used applications of kernel PCA.

All experiments reported were carried out using the RBF kernel. It is important to mention that the kernel should be bounded for these robust methods to work. The machine used is a Pentium 4, 2.8 GHz, 1GB RAM. The values of $\epsilon$ and $h$ were obtained using the heuristic proposed in Figure 3, setting $\epsilon$ such that 10% of the score values lie within the epsilon insensitive range and setting $h$ such that 90% of the score values lie within the range $-h < \epsilon < h$.

A. Experiment 1 - Denoising

The first experiment consists of a denoising application. Simulations were done with a curve-shaped dataset in two dimensions and with the UCI multiple features handwritten digit dataset. The curve dataset consists of 360 data points for training, 420 for validation and 320 for testing. The loss function parameters $\epsilon = 0.34, h = 3.7$ were set according to Figure 3. Model selection surfaces for the curve dataset can be seen in Figure 4 showing that in the weighted kernel PCA method, the criterion saturates with respect to the number of components $N_c$. On the other hand, in kernel PCA, the variance of the projected variables is always increasing with respect to $N_c$. This means that fewer components have to be computed in the weighted kernel PCA algorithm. Figure 5 shows a slice of the surface plots. The values of the proposed criterion and the kernel PCA criterion (variance) were rescaled for graphical purposes. Obtained parameters are $\sigma^2 = 0.45, N_c = 40$ for kernel PCA and $\sigma^2 = 2.0, N_c = 8$ for the SQP algorithm. Sparseness of the proposed method can be seen in Figures 6 and Table I. Note that sparseness varies from component to component. However, most of the outliers are not support vectors therefore they can be removed from the dataset. Table II shows the percentage of outliers present in the support vector set.
The reduced set selection method [4] is more sparse than the proposed methods but its support vector set contains almost all outliers. The components found by the SQP algorithm are more sparse than the components obtained by the simplified weighting scheme but at a more expensive computational cost.

The handwritten digit training set is composed of 195 digit images of $15 \times 16$ pixels. The validation set consists of 40 digits. We added outliers and Gaussian noise to the dataset and set $\epsilon = 0.1, h = 4$ according to Figure 3. Figure 8 shows the slices of the model selection surfaces with similar results compared to Figure 4. Obtained parameters are $\sigma = 350, N_c = 190$ for kernel PCA and $\sigma^2 = 300, N_c = 120$ for the SQP algorithm. The denoising results can be seen in Figures 9 and 10 showing improved results of the SQP algorithm compared to kernel PCA in terms of robustness together with visually appealing digits. Table III shows the mean squared error (MSE) and standard deviation for kernel PCA and the proposed methods with respect to the three pre-image algorithms. The MSE was calculated between the denoised digits and the test set without outliers and Gaussian noise. Figure 11 shows sparseness results in terms of accumulated number of support vectors with respect to the number of components.

B. Experiment 2 - Feature Extraction

The feature extraction experiment was carried out with a square-shaped dataset in two dimensions consisting of 1000 data points. The weighted kernel PCA algorithm was used. The training scenario consisted of 300 data points for training, 300 data points for validation and the remaining 400 data points for testing. We included outliers and performed 10 randomizations of the training and validation sets. The parameters of the loss function were set to $\epsilon = 0.5, h = 3$. Model selection surfaces and slices were obtained in a similar way as in the previous experiments. Selected parameters are $\sigma^2 = 0.45, N_c = 6$. Figures 12 and 13 show the feature extraction results for kernel PCA and weighted kernel PCA respectively. The contours of constant score value are shown in different levels of gray. We can see that in kernel PCA some feature values are completely determined by the outliers which is not the case in weighted kernel PCA.

IX. Conclusion

A new kernel PCA formulation for general loss functions was derived. This formulation is based on the LS-SVM context and can be used to impose desirable properties such as sparseness and robustness in the analysis. These two properties are missing in the classical kernel PCA because it has an associated $L_2$ loss function, and the solutions are expressed in terms of dense kernel expansions. To overcome these issues, we proposed a loss function with an epsilon insensitive zone for sparseness and bounded score function for robustness. We have shown two different algorithms to obtain components using this loss function. The first algorithm solves a set of nonlinear equations using an SQP method. This nonlinear solver was initialized using classical kernel PCA eigenvectors/values which were shown to be good initial starting points leading to convergence in most cases. However, we only consider the first local solution obtained through this initialization while other local optima may be interesting as well. The second algorithm is a simplified iterative weighting scheme that leads to a sequence of generalized eigenvalue problems which
can be solved efficiently. We proposed a model selection criterion based on our constrained optimization framework to obtain the kernel parameters and the number of components. A heuristic to find good choices of the loss function parameters was also discussed. While mutual orthogonality of the scores variables in classical kernel PCA implies mutual orthogonality of the eigenvectors, that is not the case with a general loss function. However, orthogonality constraints can be added to the primal optimization problem. From simulations results, the proposed methods showed good performance in terms of robustness together with a sparse representation. The components obtained by the SQP algorithm were shown to be more sparse than the components found by the weighted approach. However, the latter algorithm was shown to be faster in terms of computation times.
