Abstract

Metamodels are the central artifacts in Model-Driven Engineering and like any other software artifact, subject to constant change. This fact necessitates the co-evolution of dependent artifacts such as models and transformations to resolve induced inconsistencies. While the co-evolution of models has been extensively studied, the co-evolution of transformations and especially OCL expressions being a substantial part thereof have been less examined so far. To fill this gap, this paper proposes resolution actions for all atomic metamodel changes violating the syntactic correctness of OCL expressions, thus, being able to resolve induced inconsistencies. Thereby, the resolution actions establish an emulated view on the evolved metamodel such that syntactic correctness is re-established. To verify the semantic correctness of the resolution actions, we use our PaMoMo language, allowing us to specify semantic correctness requirements for model transformations. Finally, to demonstrate the applicability of our approach, a proof-of-concept prototype based on ATL is provided.

1 Introduction

Model-Driven Engineering (MDE) proposes the use of models to conduct software development on a higher level of abstraction [2]. Thereby, model transformations play a vital role for systematic transformations of models conforming to different metamodels (MMs), which describe the syntactic constraints for models, i.e., the abstract syntax thereof. Like any other software artifact, MMs are subject to constant change, i.e., they evolve, caused by, e.g., changing requirements. During evolution, the conformance between the MM and the dependent artifacts may be violated, which demands for a co-evolution of the dependent artifacts to resolve induced inconsistencies.

While the automated co-evolution of models has been subject to extensive research in the past (cf. [12] for a survey), the automated co-evolution of transformations has been less examined so far. Although some early work exists (cf., e.g., [6, 8, 9, 16]), in particular the co-evolution of Object Constraint Language (OCL) [25] expressions has not been a major focus up to now, although OCL expressions make up substantial parts of model transformations [29]. The indispensable role of OCL stems from the fact that OCL expressions allow to perform complex queries on the input models, which are essential, since the results thereof are used in two important parts, namely in assignments, e.g., to produce the target model, and in steering the control flow, e.g., in case of conditions. Consequently, they represent a significant ingredient in rule-based model transformation languages, such as ATL [14] or QVT [24].

To enable the co-evolution of OCL expressions in model transformations, this paper proposes resolution actions for all atomic MM changes violating the syntactic correctness of OCL expressions. Thus, this paper continues the work described in Kusel et al. [17], where we proposed a complete and minimal set of atomic changes, which has been systematically derived from Ecore\(^1\), thereby enabling the definition of arbitrary evolutions of Ecore-based MMs. This set of changes has been analyzed regarding its impacts on OCL expressions, thereby dividing the set of changes into those breaking the syntactic correctness of OCL expressions and those that do not. For breaking changes resolution actions are proposed, establishing a view on the evolved MM emulating the old version of the MM to the transformation definition, such that syntactic correctness is re-established. Whenever an automatic resolution is not possible, the user may specify appropriate resolution actions being supported by respective templates. The proposed resolution actions ensure both, syntactic correctness, which can be statically checked by a compiler, as well as semantic correctness by preserving the old version of the target model as far as possible, which we verify by dedicated properties expressed in our “Pattern-based Modeling Language for Model Transformations” (PaMoMo) [10]. Finally, to provide a proof-of-concept, the proposed resolution actions are implemented by means of Atlas Transformation Language (ATL) [14] helpers and demonstrated using a running example.

The paper is structured as follows: Section 2 briefly introduces model transformations and the role of OCL, while in Section 3 MM evolution and its impacts on OCL are discussed. Resolution actions for breaking changes are proposed in Section 4, while the formalism to check their semantic correctness is presented in Section 5. Lessons learned are discussed in Section 6, before related work is surveyed in Section 7. Section 8 concludes the paper.

2 Role of OCL in Model Transformations

This section briefly introduces model transformations in general as well as the role and importance of OCL expressions therein in particular. Although OCL might also be used in other contexts, e.g., to specify MM constraints [4] restricting the instantiability of the MM, we focus on the

\(^1\) http://www.eclipse.org/modeling/emf
co-evolution of OCL expressions in model transformations. Nevertheless, this work might also be applied to other application contexts.

2.1 Model Transformations in a Nutshell

Model transformations aim at transforming source models conforming to a source MM to target models conforming to a target MM, whereby both MMs conform themselves to a meta-metamodel, e.g., Ecore, being the Eclipse realization of MOF [23]. Consequently, transformation definitions describing model transformations must conform to these two MMs in addition to the transformation MM including the OCL MM, which specifies the syntax of transformation definitions. Syntactic correctness of a model transformation may be checked by an appropriate compiler, while the semantic correctness may be verified by given requirements the transformation has to fulfill. To define such requirements, our PaMoMo language may be utilized (see Section 5).

To give an example of a model transformation, Figure 1 provides a small excerpt of the well-known Class2Relational transformation. Please note that despite its simplicity, it is nevertheless able to serve as a running example throughout this paper. The given transformation definition states that persistent classes should be transformed into tables and attributes into columns by two dedicated transformation rules. In order to avoid code duplication, common transformation parts have been extracted to a separate base-rule Element2Named, containing the assignment of ids of elements. The lower part of Figure 1 shows a concrete model describing a persistent class Person comprising three attributes, i.e., id and Age of type Integer as well as Fullname of type String. This model serves as input for the transformation engine, which outputs a model, comprising a Table with name University.Person and three columns resulting from the attributes.

In this work, OCL expressions are used in two indispensable roles [16]. First, OCL is used in bindings to query source model elements, which are employed to produce the target model (cf., e.g., ".e.package+=", ";e.id" calculating the values for the target attribute "table.name"). Second, OCL is utilized in conditions to steer the control flow (cf., e.g., ".e.persistent!=true" to transform persistent classes, only). Thus, OCL expressions constitute large parts of transformation definitions [29] and by this play an essential role.

As already stated above, OCL may also be used to constrain the instantiability of MMs. The exemplary constraints shown in Figure 1 state that for the attribute Element.id a value must be set as well as that the value of the attribute Class.persistent must be either 0 or 1. Please note that the co-evolution of OCL constraints is not in the focus of this work, as already stated above.

Although transformations must conform to three MMs, OCL expressions depend on the source MM by means of a so-called "domain conforms to"-relationship [21] and the OCL MM by means of a "conforms to"-relationship [14], only. This is because OCL expressions are used to query source models and do not refer to the target MM. Thus, this paper focuses on the evolution of the source MM and the co-evolution of OCL expressions.

3 Metamodel Evolution and its Impacts on OCL Expressions

This section discusses the challenge of MM evolution and arising impacts on OCL expressions. For details, the interested reader is referred to Kusel et al. [17], where we provide an in-depth analysis of this topic.

3.1 Metamodel Evolution

Like any other software artifact, MMs are subject to constant evolution, e.g., due to needs for (i) adaptation caused by changing software environments, (ii) perfection induced by user requirements, or (iii) correction because of errors [19]. A particular MM evolution may be described by dedicated changes that lead to a new version of the MM.

To exemplify this, an evolution of the running example is shown in the left part of Figure 1. Thereby, a new version of the source MM has been created by seven dedicated changes. First, a new class Type has been created (1 in Figure 1) as well as a new reference Type.package (2 in Figure 1) connecting the new class. Furthermore, the attribute Type.package has been moved to this new class (3 in Figure 1). In addition to that, the attribute Class.package has been deleted (4 in Figure 1) and the attribute Class.id has been renamed to Class.name (5 in Figure 1). Finally, the reference Class.attr has been set to be unordered (6 in Figure 1) and the type of the attribute Class.persistent has been changed from Int to Boolean (7 in Figure 1).

When analyzing the impacts of these changes on the occurring OCL expressions, one might recognize that all changes except the two constructive changes (1 and 2 in Figure 1) have a breaking impact on the OCL syntax and thereby prevent a successful execution of the existing model transformation. Consequently, a co-evolution of the OCL expressions is needed by employing dedicated resolution actions. Before discussing potential resolution actions, the questions which changes may arise at all and which of them might have a breaking impact on OCL expressions are discussed subsequently.

3.2 Complete and Minimal Set of Changes

To be able to describe arbitrary evolutions and analyze their impacts on OCL expressions, a systematic set of atomic changes has been derived from Ecore [17] which is briefly summarized in the following. This set of changes fulfills two criteria – completeness to allow for any possible change and minimality to avoid the analysis of overlapping changes as may be the case for composite changes. Basing on the Ecore meta-MM, all potential constructive and destructive changes have been derived by resorting to all concrete meta-classes, e.g., EClass. In addition to that all potential update changes have been derived by referring to all meta-features, e.g., EClass.abstract. Figure 2 shows the resulting set of atomic changes.

This set of changes has been analyzed according to its effects with respect to structural complexity (SC), i.e., the number of instantiable types, and information capacity (IC), i.e., the potential number of valid model instances, since these two criteria are significant for the impacts on OCL expressions as well as subsequently for resolution. Thereby, changes affecting SC indicate impacts in accessing MM elements in OCL expressions and have been evaluated by counting the number of all instantiable types according to [27]. In contrast, changes concerning IC indicate impacts on the result set of OCL expressions and have been evaluated by counting the potential number of all valid instances of a MM following [22]. These two criteria are able to partition the set of update changes into six groups according to their behavior, which are used to analyze impacts and resolution actions in the following. The resulting groups comprising (1) renaming updates, (2) moving updates, (3) relaxing updates, (4) restricting updates, (5) constructive updates, and finally, (6) destructive updates may be found in Table 2.

3.3 Impacts on OCL Expressions

In order to know which atomic changes of the systematic set of changes require resolution, the impacts of changes on OCL expressions are summarized in this section. Thereby, we distinguish between non-breaking changes, i.e., those not affecting the syntactic correctness of OCL expressions, and breaking changes. Please note that the evaluation assumes that changed MM elements have been used by at least one OCL expression and the worst case scenario is considered, i.e., changes are evaluated as breaking, if there exists at least one case that breaks the syntactic correctness of the OCL expression. The results of the evaluation are presented in Table 2.
original transformation should be preserved as far as possible, i.e., semantic correctness should be ensured by the resolution actions, which means in our case the preservation of the specified requirements the transformation has to fulfill. While the achievement of syntactic correctness may be verified automatically by a compiler, the verification of semantic correctness is more challenging and, thus, will be discussed in detail in Section 5. Third, resolution actions must be consistent with the co-evolution of other dependent artifacts, like model co-evolution as well as semantic requirements of the co-evolution.

4.2 Conceptual Approach

For achieving syntactic correctness as well as semantic correctness, we propose a conceptual approach that establishes an “emulated view” on source MM\(_1\) (see Figure 3), which basically maps the newly structured input models conforming to the source MM\(_1\) such that they appear to the transformation in the original structure, i.e., conforming to the source MM\(_0\). Consequently, this approach tries to re-establish the information contained in the original source MM\(_0\) on basis of the information still available in the new source MM\(_1\). Thus, differently structured information might be recovered automatically by dedicated resolution actions (e.g., the information of the attribute Attribute\_type might be recovered by accessing Type\_type instead). However, one might recognize that deleted information can not be restored automatically and, consequently, demands for user intervention in the resolution process (e.g., the information contained in the attribute Class\_package is lost as exemplified by the change 3 “Delete Attribute” in Figure 1).

One may see that this approach is able to ensure syntactic correctness, since the view emulating MM\(_0\) is compatible with the original transformation definition. Thereby, it also ensures semantic correctness by preserving the specified correctness requirements (see Section 5). The original transformation is extended by ATL helpers, only, realizing the emulated view approach, which restores all the information still available in MM\(_1\) or demands for user intervention otherwise.

4.3 Proof-of-Concept Realization

In this section, a proof-of-concept realization of the conceptual approach is presented. Although this implementation relies on ATL, the conceptual approach is not limited to a certain transformation language.

For realizing the emulated view, basically two approaches might be followed. First, the resolution actions realizing the view may be “inlined”, i.e., the original transformation gets adapted at the corresponding positions, being closely related to program transformation [28]. Second, the resolution actions realizing the view may be implemented by the concept of ATL helpers, without modi-

Figure 3: Exemplary Emulated View
fying the original transformation definition, being related to data transformation [18]. Since the first approach has the disadvantage that the border between the original transformation and the resolution actions gets blurred and by this hinders a subsequent manual adaptation, we decided for an approach based on data transformation. This allows us to keep the resolution actions separated and, thus, facilitates understandability as well as maintainability by the user. For realizing the helper approach, the transformation has to be adapted marginally by adding an empty parameter list to accesses of the affected elements in order to redirect the accesses to the helpers, e.g., calling cl.package() instead of cl.package. In the following, the proposed ATL helpers realizing the resolution actions for each breaking change are presented. Thereby, the general idea behind the resolution actions is discussed, before an example as well as the generic templates for building the helpers are provided.

### 4.3.1 Destructive Changes

All destructive changes invalidate OCL expressions that access the deleted elements. Since the information held by the deleted elements is lost, it might not be restored automatically in the emulated view. However, a generic template is provided to support the user in the resolution process. For example, the user may decide to compensate the deletion of attribute Class.package (\( \ominus \)) in Figure 1) by a substitution with an empty String, resulting in Listing 1.

#### Listing 1: Resolution Action for Destructive Updates

```java
-- resolution action
helper context Class2Table
  def \( \langle \text{Class} : \text{Class}! \rangle \text{packag}() : \text{String} = 3 \)
  \( \langle \text{user-defined resolution} \rangle \)
-- transformation definition
rule ClassTable extends Element2Named {
  from cl : Class! \text{Cl} \{ \text{cl.persistent} = 1 \}
  to table : RelationalTable {
    name \( \leftarrow \text{cl.packag}() \), \( + \leftarrow \text{id} \),
    col \( \leftarrow \text{cl.attrib} \),
    key \( \leftarrow \text{cl.attrib} \rightarrow \text{first}() \)
  }
}
```

The generic template for creating the concrete helper is shown in Listing 2. Thereby, the context of the helper is set to that EClass the deleted feature was originally contained in, i.e., feature0.eContainingClass. The name of the helper defined by “def” is the name of the original feature, i.e., feature0.name, and its return type is set to the original type, i.e., EDataType. The body of the helper provides a place-holder for a user-defined resolution action.

#### Listing 2: Template for Destructive Changes of EStructuralFeature

```java
-- template for resolution action
helper context <feature0.eContainingClass> def :
  <feature0.name> () : <feature0.type> =
  <user-defined resolution action>;
```

Please note that the deletion of an EClass or EDataType might not be compensated with this approach in ATL, since ATL does not allow for “emulated classes”, which

would be needed to emulate the deleted MM elements. Furthermore, all OCL operations that operate directly with type definitions, i.e., `oclAsType(T)`, `oclIsTypeOf(T)`, `oclIsKindOf(T)`, and `oclIsAllInstances()`, can not be resolved automatically, and thus, require user intervention by, e.g., substituting the deleted type with another one.

### 4.3.2 Update Changes

In the following, resolution actions for update changes with update impact are proposed.

**Group 1: Renaming Updates:** Each renaming update has breaking impact on the OCL expressions that access the renamed element. Thus, a resolution action is needed, which returns the renamed element. Listing 3 shows the resolved transformation definition change of "Rename Attribute" (4) in Figure 1) of the running example.

```
Listing 3: Resolution for Rename
```

1 -- resolution action
2 helper context ClassD!Element def : id() : String =
3 self.name;
4
5 -- transformation definition
6 abstract rule Element2Named |
7 from elem : Class!Element
8 to named : Relational!Named {
9 name <- elem.id();
10 }
```

The generic template for this helper is shown in Listing 4. The context of the helper is set to its original containing class, the name of the helper is set to the original name, and the return type is set to its original datatype. In the body of the helper the value of the renamed element is returned. Please note that renaming of `EClasses` and `EDataTypes` may not be resolved in ATL using this approach, since ATL does not support the definition of evaluated classes, as stated above. However, renaming of those may be resolved by program transformation.

```
Listing 4: Template for Renaming Updates
```

1 -- template for resolution action
2 helper context `<featureV0.eContainingClass> def : <featureV0.name>() : String =
3 self.<featureV0.name>;
4
5 -- transformation definition
6 abstract rule Element2Named |
7 from elem : Class!Element
8 to named : Relational!Named {
9 name <- elem.id();
10 }
```

**Group 2: Moving Updates:** While renames change the identifier under which the information may be accessed, moving updates change the position from where the information may be obtained. Consequently, moves always entail a breaking impact, while being again automatically resolvable by the emulated view without any loss of information. For realizing the emulated view, the original path has to be adapted to redirect to the new location of the moved element. Thus, the change "Move Attribute" (5) in Figure 1) of our running example is resolved by a helper that is responsible for this redirection (see Listing 5). Therefore, the new navigation path is defined in the body of the helper, starting from the element itself along the reference type to the original feature type.

```
Listing 5: Resolution for Moving Update
```

1 -- resolution action
2 helper context ClassD!Attribute def : type() : String =
3 self.<type>;
4
5 -- transformation definition
6 rule Attribute2Column extends Element2Named |
7 from attr : Class!Attribute
8 to col : Relational!Column |
9 type <- attr.<type>;
```

The template for moving updates is shown in Listing 6. In this template, the context and return type are set to the original types, while the name of the helper is set to the name of the moved feature with an empty parameter list.

In the body of the helper, the newly created reference is added in order to navigate over this reference to the moved feature.

```
Listing 6: Template for Moving Updates
```

1 -- template for resolution action
2 helper context `<featureV0.eContainingClass> def :<featureV0.type>() : String =
3 self.<featureV0.name>;
4
5 -- transformation definition
6 abstract rule Element2Named |
7 from elem : Class!Element
8 to named : Relational!Named {
9 name <- elem.id();
10 }
```

In case of inlining a feature, i.e., moving it along a reference inside the class from which the feature navigated stems, we suggest to optimize the navigation by removing this indirection. This optimization prevents vulnerability with respect to a potential deletion of the references in the future, which is, e.g., entailed in a composite change like "Inline Class".

**Group 3: Relaxing Updates:** Relaxing updates may have breaking impact on OCL expressions, since they might cause changes to OCL datatypes as introduced before (see Table 1). The potential datatype changes may be classified into three cases: (i) collection type to collection type, (ii) single-valued element to collection type; and (iii) generalizing a reference- or attribute-type. The emulated view approach allows to automatically resolve (i) and (ii) by casting the changed OCL types back to their original types. While for casts between a collection with ordering information and a collection without ordering information (cf. case (i)), the original ordering information might have been lost during model co-evolution, for the cast from a collection type to a single-valued element (cf. case (ii)), no information loss occurs in case that still at most a single element is contained in the collection after model co-evolution. Consequently, although syntactic correctness might be achieved by the emulated view approach, semantic correctness in the strict sense of remaining the observable behavior is not guaranteed, since the inputs might have been changed during model co-evolution, which demands a relaxed notion of semantic correctness as discussed in Section 5. If no appropriate cast operation is available (cf. case (iii)), user intervention is required.

**Case (i): Collection Type to Collection Type.** For the change "Change Ordered" in the running example (6) in Figure 1), this means to cast the type of the reference `attr` back to its original type, i.e., `OrderedSet`, which is demonstrated in Listing 7.

```
Listing 7: Resolution of Collection Type Change
```

1 -- resolution action
2 helper context ClassD!Class def : attr() : OrderedSet( ` ` Class!Attribute) =
3 self.<attr>.orderedSet();
4
5 -- transformation definition
6 rule Class2Table extends Element2Named |
7 from cl : Class!Class (cl.persistent = 1)
8 to table : Relational!Table |
9 name <- cl.package + "." + cl.id,
10 col <- cl.<attr>
11 key <- cl.<attr>.first();
```

The template to generate helpers for casting the OCL collection types is shown in Listing 8. Thereby, the return type is set to the original type of the collection. In the body of the helper the corresponding cast to the original type of the feature is determined by checking the new type of the collection and applying the corresponding cast operation on this type.

```
Listing 8: Template for OCL Collection Type Casts
```

1 -- helper variable
2 <var collectionName = self.<featureV0.name>;>
3 -- template for resolution action
4 helper context `<featureV0.eContainingClass> def :<featureV0.type>() : String =
5 self.<featureV0.name>;
6
7 if (collectionName.oclIsTypeOf(OrderedSet)) then>
8 }
Case (ii): Single Valued Element to Collection. Relaxing updates also comprise the increase of the upperBound from 1 to > 1, which causes the underlying OCL type to change from T to Collection(T). As a consequence, the operations applied on elements of type T are now invalidated, since the OCL datatype changed to a collection.

Listing 9 shows the template for an ATL helper to extract a single valued element from a collection. In the body of the helper, an arbitrary element from the collection is selected and returned.

Listing 9: Template for Extracting a Single Element from a Collection

```java
1 template for resolution action
2 helper context <featureV0.eContainingClass> def : =
3 <featureV0.name>() : <featureV0.type> =
4 self. <featureV0.name()>->any()
```

Case (iii): Generalizing a Datatype. In order to cope with type generalizations, an appropriate cast operation has to be defined by the user employing the template already shown in Listing 2.

Group ⑤: Restricting Updates: Analogous to relaxing updates, restricting updates may also have breaking impacts on OCL expressions, since the employed OCL datatypes may have changed. Again three cases might be distinguished according to the arising type change: (i) collection type to collection type, (ii) collection type to single valued element, and (iii) incompatible reference- and attribute-type changes. The emulated view approach compensates those cases with corresponding casts.

Case (i): Collection Type to Collection Type. The template for resolution has already been presented in Listing 8 and may be applied to this case as well.

Case (ii): Collection Type to Single Valued Element. In case of decreasing the upperBound from > 1 to 1 the underlying OCL type changes from Collection(T) to T causing the invalidation of collection operations such as first(). Thus, the corresponding resolution action is to wrap the now single valued element into its former collection type.

Listing 10 shows the template for a helper, which turns a collection containing a single element, i.e., the original value of the feature.

Listing 10: Template for Single Valued Element to Collection

```java
1 template for resolution action
2 helper context <featureV0.eContainingClass> def : =
3 <featureV0.name>() : <featureV0.type> =
4 self. <featureV0.name()>;
```

A collection might also be downsized by decreasing the upperBound from a value > 2 to a value > 1. This change has breaking impact on OCL expressions which access elements directly by their index, i.e., the operation at(index). If the index is greater than the upperBound, the transformation will break, because the access is out of bounds. However, since an automatic resolution action can only guarantee syntactic correctness by setting the index between 1 and lowerBound, thereby ensuring a return value for this operation, in this case user intervention is required to redefine the index.

Case (iii): Incompatible Type Changes. Type changes may introduce a destructive effect, e.g., changing the type from Integer to Boolean as done by the change “Change Type” (② in Figure 1), since these types are not in an inheritance relationship. As there is no dedicated cast operation for Integer values to Boolean values in OCL, user intervention is required to specify a suitable cast operation. A potential user-defined resolution action is shown in Listing 11, while the template is provided in Listing 2.

Listing 11: Resolution of Type Change

```java
1 -- resolution action
2 helper context ClassD!Class def : persistent() :
3 if (self.persistent = true) then 1 else 0 endif;
4 -- transformation definition
5 rule Class2Table extends Element2Named {
6 from cl : Class!Class (cl.persistent = true)
7 to table : RelationalTable {
8 name <- cl.package + "." + cl.id,
9 col <- cl.attr,
10 key <- cl.attr->first() }
11 }
```

5 Ensuring Semantic Correctness of Co-Evolved Model Transformation Definition

As discussed previously, resolution actions must ensure syntactic as well as semantic correctness. While the former may be easily verified by a compiler, the verification...
of the latter is more challenging. Thus, this section dis-
cusses notions of semantics and introduces a formalism
for the automatic verification of semantic correctness.

5.1 Notions of Semantics

When surveying dedicated literature, ideas for the verifica-
tion of semantic correctness may be found for a restricted
set of change operations, namely for refactorings, only.
Thereby, a refactoring is said to be semantically correct,
if the structure of a program or model is changed with-
out changing its observable behavior [26]. For verifying
the semantic correctness, regression testing is a common
mechanism [7].

Consequently, regression testing may be applied to
verify semantic correctness of refactorings of MMs and
coevolved transformations as well. However, there are
changes in our complete and minimal set of changes that
go beyond refactorings, e.g., destructive changes. Conse-
quently, a more general approach is desirable, which re-
laxes the strong condition of demanding exactly the same
observable behavior. Thus, we propose to verify seman-
tic correctness by dedicated properties expressed in our
PaMoMo language [10], which must be fulfilled by a
transformation definition, thereby relaxing the strong con-
tion of exactly same observable behavior and by this,
Enabling for the verification of semantic correctness for
all changes of our complete and minimal set of changes.

5.2 PaMoMo for Verifying Semantic Correctness

Originally developed for testing model transformations,
our PaMoMo language provides a visual, declarative, for-
mal specification language to describe correctness require-
ments for transformations. PaMoMo specifications allow
to express what a transformation should do, but not how
it should be done, thus, the mechanism may be used to
specify requirements for semantic correctness as well.

5.2.1 PaMoMo in a Nutshell

A PaMoMo specification consists of declarative visual
patterns, which may be positive or negative. Positive pat-
terns (denoted by a “P”) describe necessary conditions to
be fulfilled (i.e., the pattern is satisfied by a pair of models,
if these contain certain elements) while negative ones (den-
noted by an “N”) state forbidden situations (i.e., the pattern
is satisfied, if certain elements are not found). Patterns are
composed of two compartments containing object graphs.
The left compartment contains objects typed on the source
MM, while the objects to the right are typed on the tar-
et MM. Objects in the source and target compartments
may have attributes that may be assigned either a concrete
value or a variable. A variable may be assigned to several
attributes to ensure equality of their values.

The specified patterns provide a well-defined opera-
tional semantics on basis of QVT-Relations [24], which
allows to check whether pairs of input models and re-
sulting output models fulfill the specified correctness re-
quirements, which in consequence allows to evaluate the
semantic correctness of a transformation definition. For
further details about PaMoMo, the interested reader is re-
ferred to [10].

5.2.2 PaMoMo for the Running Example

Figure 4 shows three PaMoMo patterns that specify re-
quirements regarding the semantic correctness for the
original Class2Relational transformation. Thereby, the pos-
tive pattern PersClass2Table demands that for each Class
object that is marked as being persistent (persistent=1) in
a given source model, a corresponding Table object with
Figure 4: PaMoMo Patterns for Class2Relational

Figure 5: Co-Evolved PaMoMo Patterns

the same name (see the bound variable X) must exist in a
transformed target model. Furthermore, the negative pat-
ttern NonPersClass2Table demands that for each Class ob-
ject that is not marked as being persistent (persistent=0)
in a given source model, no corresponding Table object must
exist in a produced target model. Finally, the pattern At-
btribute2Column demands that for each Attribute object of a
persistent Class object in a source model, a corresponding
Column object must exist in a transformed target model.

In order to be able to verify the semantic correctness of
the co-evolved model transformation, the PaMoMo pat-
terns must be co-evolved as well. Since PaMoMo patterns
are specified by means of object graphs, the co-
evolution strategy employed for existing models may be re-
used for this task by a dedicated model co-evolution
tool such as COPE [13] assuming that the patterns are
model fragments of the corresponding domain MMs, re-
sulting in the PaMoMo patterns shown in Figure 5. One
might recognize that destructive changes entail a deletion
of the corresponding parts of the patterns, thereby relax-
ing the requirements for semantic correctness. By this,
unbound variables on the target side of the patterns may
arise, such as “Y” in the pattern Attribute2Column, which
formerly demanded for the assignment of the name of the
package to the name of a table. As long as the variable
remains unbound, it serves as a wildcard. However, if the
user decides to replace the deleted package name, i.e., “Y”,
by an empty string, then the resolution action has to use
the same value, i.e., an empty string, for the transforma-
tion definition to produce models that match this pattern,
t.e., being semantically correct. The co-evolved patterns
may then be used to check, if the co-evolved transforma-
tion maintains semantic correctness by checking if pairs of
input models and produced output models fulfill the re-
quirements stated by the PaMoMo patterns.

In summary, PaMoMo allows to specify correctness re-
quirements for model transformations, thereby explicating
semantic correctness and by this providing a formalism
to verify the semantic correctness of a co-evolved model
transformation.
6 Lessons Learned

This section discusses the proposed approach by dedicated lessons learned.

Realization of a Emulated View is Restricted in ATL

As discussed in Section 4, our approach establishes an emulated view on MM parameters for resolution such that the input models appear to the transformation in the original structure, i.e., conforming to the source MM. Although this conceptual approach is able to restore syntactic and semantic correctness in general, the concrete realization based on ATL helps is restricted, since ATL’s view capabilities support emulated features only, whereas emulated classes are not supported. Thus, changes affecting classes have to be resolved by a “program transformation” realization in ATL, demanding a hybrid approach.

Breaking Changes Inducing an Information Loss Demand for User Intervention.

Changes may be classified according to their potential of inducing information loss. Thereby, constructive changes, renaming updates, moving updates, relaxing updates as well as constructive updates never induce information loss. In contrast, destructive changes, restricting updates, and destructive updates always induce information loss assuming the existence of corresponding instances. Since lost information can not be re-established automatically, those changes with breaking effect on the syntax always demand for user intervention, except when automatic casts are possible as in case of some kinds of restricting updates.

PaMoMo Enables Checking of Semantic Correctness for Arbitrary Changes.

As already mentioned, semantic correctness may be specified by dedicated input models and corresponding expected output models, i.e., by specifying the observable behavior of a transformation. Consequently, a co-evolution may be said to be semantics preserving, if the observable behavior has not been changed. However, this methodology is only applicable to changes that do not interfere with the observable behavior, i.e., refactorings, while all other changes might not be semantics preserving according to this restrictive definition. PaMoMo relaxes this restrictive definition by not specifying the observable behavior by hard-coded pairs of input/output models but instead by stating properties the models must fulfill. Consequently, PaMoMo enables the checking of semantic correctness for arbitrary changes.

7 Related Work

We will now compare our work to other approaches, with respect to its focus, supported changes, impact analysis on OCL, syntactic and semantic resolution of breaking changes, and the availability of a prototypical implementation (see Table 3).

Regarding the focus of co-evolution in a specific technical space, two groups of approaches with respect to their usage of OCL exist. Most closely related, the first group of approaches targets the co-evolution of transformations employing OCL expressions [8, 9, 16], all of them in the technical space of Ecore, whereby the co-evolution of the OCL part is considered particularly by only one of them [9]. More widely related since not focusing on OCL in model transformations but still facing the same problems in OCL co-evolution, the second group concentrates on resolving inconsistent OCL constraints as parts of UML class diagrams [5, 15, 20], and one exception based on MOF [11].

Considering the supported changes, six approaches [5, 8, 9, 11, 15, 16] partially allow for constructive changes, five of those [8, 9, 11, 15, 16] partially consider destructive changes, and update changes are partially supported by all approaches. Thus, in contrast to our approach, no approach covers a complete change set. However, the surveyed approaches additionally consider composite changes, which will be one line of future work as detailed below. By concentrating on composite changes, no approach presents a minimal change set, which is different to our work providing a systematically derived, minimal set of atomic changes.

Regarding the impact on OCL, four approaches [9, 11, 16, 20] consider breaking and non-breaking impact on the syntax, whereby one of them [9] only considers impacts partially.

Considering resolution, all approaches take care of syntactic correctness, i.e., they syntactically resolve the induced inconsistencies. Regarding semantic correctness, five approaches [8, 9, 11, 15, 16] do not provide any means for automatic verification, but partially rely on refactorings, for which the according resolution actions are defined in literature (cf., e.g., [7]). One approach does not discuss semantics but instead refers to [1], in which the semantics preservation for one refactoring, i.e., Move Attribute, is proven. One approach [5] employs regression testing, being most closely related to our approach.

Finally, six approaches [5, 8, 9, 11, 16, 20] provide an implementation, while a sole approach is conceptual only. A full implementation of the work presented in this paper based on EMF is in progress, while the proof-of-concept has already been presented in Section 4.

In summary, one may see that the work presented in this paper is unique with respect to completeness and minimality of changes and, consequently, provides an entire examination of changes. Furthermore, resolution actions have been proposed for all breaking changes.

8 Conclusion & Future Work

In this paper, (semi-)automatic resolution actions for the co-evolution of OCL expressions in model transformations in response to MM evolution have been proposed, building upon the work presented in [17]. In the course of this paper, several lines of future work have been identified. First, we plan on investigating composite changes including refactorings, which may affect more than one MM element, therefore resolution actions have to be combined, accordingly. Second, we will examine how the ATL helpers realizing the emulated view may have to be adapted in case of changes on the same MM element in a series of evolution steps. For this, initial ideas for optimizing ATL helpers have already been discussed in Section 4. Finally and third, the prototypical proof-of-concept implementation will be extended to a comprehensive tool based on EMF for impact analysis and co-evolution of OCL expressions in model-transformations.
