Keywords: spacetime shape, radon transform, distance transform, shape descriptor

Abstract: A novel algorithm has been proposed for recognizing human actions using a combination of shape descriptors. Every human action is considered as a 3D space time shape and the shape descriptors based on the 3D Euclidean distance transform and the Radon transform are used for its representation. The Euclidean distance transform gives a suitable internal representation where the interior values correspond to the action performed. By taking the gradient of this distance transform, the space time shape is divided into different number of levels with each level representing a coarser version of the original space time shape. Then, at each level and at each frame, the Radon transform is applied from where action features are extracted. The action features are the R-Transform feature set which gives the posture variations of the human body with respect to time and the R-Translation vector set which gives the translatory variation. The combination of these action features is used in a nearest neighbour classifier for action recognition.

1 INTRODUCTION

Human action recognition has been a widely researched area in computer vision as it holds a lot of applications relating to security and surveillance. One such application is the human action detection and recognition algorithm implemented in systems using CCTV cameras where the system is used for detecting suspicious human behavior and alerting the authorities accordingly (C.J.Cohen et al., 2008). Another area is in object recognition where, by evaluating the human interaction with the object and recognizing the human action, the particular object is recognized (M.Mitani et al., 2006). Thus arises the need for faster and robust algorithms for human action recognition.

Action recognition involves the extraction of suitable distinguishable features representing certain variations in the human body caused due to the action. One approach involves the use of 2D or 3D shape descriptors to represent a space time shape which is a concatenation of human silhouettes across time. Another approach involves the computation of certain localised motion fields and trajectories of specific points from a space time shape. The various invariant properties extracted from these motion fields and trajectories are then considered as action features. In the algorithm proposed in this paper, a combination of shape descriptors are used for the representation of the space time shape and the extraction of action features. This algorithm is closely related to the action recognition framework based on Poisson’s shape descriptor (M.Blank et al., 2005) and the shape descriptor based on the Radon transform (Y.Wang et al., 2007).

In the next section, a review of the algorithms that have been proposed over the last few years for action recognition, is explained briefly. The algorithms described are mainly based on the motion fields and the shape descriptors. In the third section, the proposed algorithm for action recognition is explained in detail with illustrations. Results are provided in the fourth section where the recognition rates are compared with those of other algorithms. The variation of the accuracies with respect to certain parameters of the algorithm are also given. Finally, the paper concludes the algorithm by mentioning the pros and cons and discusses the improvements and the future work.
2 PREVIOUS WORK

In this section, we shall go through some of the works which are based on motion fields, shape descriptors and trajectories of tracked body parts.

2.1 Algorithms Based on Motion Capture Fields or Trajectories

Earlier works in action recognition makes use of temporal templates such as motion history images (J.W.Davis and A.F.Bobick, 1997), the timed motion history images (G.R.Bradski and J.W.Davis, 2000) and the hierarchical motion history images (J.W.Davis, 2003) where these templates provides the motion characteristics such as the motion history image and motion energy image at every spatial location of a frame in an image sequence. Some of the features extracted are the optical flow vectors from the MHI gradient, the radial histogram and local and global orientation computed at each pixel (G.R.Bradski and J.W.Davis, 2000). The speed of motion of a body movement was incorporated by computing the MHI from scaled versions of the images and extracting the motion fields from each level (J.W.Davis, 2003).

Motion descriptors based purely on the optical flow measurements computed from each pixel of the video frame are used to describe an action of an individual at a far off distance from the camera (A.A.Efros et al., 2003). These optical flow measurements are calculated from a figure-centric spatio-temporal volume using the Lucas-Kanade algorithm. The time variation of the optical flow vector computed is considered as an action feature which are compared by a correlation based similarity measure.

Algorithms proposed in (J.C.Niebles et al., 2006; P.Scovanner et al., 2007) consider action features as codewords in a codebook where these features are extracted from interest regions in a space time shape. In (J.C.Niebles et al., 2006), the interest regions are the local maxima regions of a response function defined by a combination of a Gaussian and a Gabor filter computed at every frame and the extracted features are the gradient and the optical flow from these regions while in (P.Scovanner et al., 2007), the interest regions are obtained by random sampling of the pixels at different locations, time and scale and the 3D SIFT descriptors extracted from these regions are taken as the action features.

Some of the works proposed a particular model which includes tracking or segmenting of various parts of the human body. In (S.Ali et al., 2007), human actions have been modelled as a non-linear dynamical system where the state variables are defined by the reference joints in the human body silhouette and their functions are defined by their trajectories. Here, action features are derived by analysing the trajectories as a time series data and extracting the invariant properties. Many methods are available for studying the time series data but the one used here applies the theory of chaotic systems to analyze the non-linear nature (J.Zhang et al., 1998).

The concept of mid-level features known as space time shapelets is introduced in (D.Batra et al., 2008) where these shapelets are local volumetric objects or local 3D shapes extracted from a space time shape. Thus, an action is represented by a combination of such shapelets as these represent the motion characteristics on a more localised level. Extracting all the possible such volumes from each space time shape of the database and clustering these sub-volumes provides the cluster centers which are then considered as space time shapelets.

2.2 Algorithms Based on Shape Descriptors

Shape descriptors (D.Zhang and G.Lu, 2003; Q.Chen et al., 2004; A.Khotanzad and Y.H.Hong, 1990; M.K.Hu, 2008) can be used to extract the variation of the silhouettes across the video frames. Better variations can be extracted using shape descriptors such as the one based on Poisson’s equation (L.Gorelick et al., 2004) and the one based on the Radon transform (S.Tabbone et al., 2006). This is because they not only give the boundary representation of a silhouette of a 3D shape but also give an internal representation. A brief discussion on these algorithms will be provided as these form the basis for the algorithm proposed in this paper.

In (M.Blank et al., 2005), the concept of a space time shape is introduced where a space time shape
is formed by the concatenation of silhouettes in the video frames and considering actions as 3D shapes. The shape descriptors based on the Poisson’s equation in 3D used to represent the space time shape and various properties such as local space-time saliency, shape structure, action dynamics and local orientation are extracted. A shape descriptor based on the Radon transform (R.N.Bracewell, 1995) known as the R-Transform is defined in (Y.Wang et al., 2007). This transform is used to represent the low-level features in a binary silhouette in a single frame and these are used in the training of hidden Markov models to recognize the action.

A combination of shape flow and motion flow features have been used as action features in (A.Mohiuddin and S.W.Lee, 2008) where the shape flow features are a combination of different moment based shape descriptors and the motion flow feature is the optical flow. The shape descriptors used are the Hu’s invariant moments (M.K.Hu, 2008) and Zernike moments (A.Khotanzad and Y.H.Hong, 1990). In (X.Sun et al., 2009), instead of using optical flow feature vectors to represent the local features, both 2D and 3D SIFT descriptors are used while the global features extracted are the Zernike moments from the motion energy images. The 2D SIFT descriptor emphasizes the 2D silhouette shape and the 3D SIFT descriptor emphasizes the motion.

4 PROPOSED ALGORITHM

The proposed algorithm is an application of the multi-level shape representation to a space time shape which provides the necessary features of action classification. The 3D Euclidean distance transform (P.F.Felzenszwalb and D.P.Huttenlocher, 2004) gives the internal representation where its gradient is used to divide the space time shape into different levels. Then, at each level, the R-Transform and the R-Translation features are extracted and these are considered as suitable action features. The various steps involved in the algorithm are explained in detail in this section.

Figure 2: Extraction of a silhouette from a video frame.

Figure 3: Space time shapes of jumping jack and walk actions.

4.1 Silhouette Extraction and Formation of Space-time shapes.

First, the silhouettes are extracted from each frame of the video sequence by comparing it with its median background and then, thresholding, dilating and eroding to form the binary silhouette image shown in Figure 2. Once the silhouettes are extracted, a predefined number are concatenated to form the 3D space time
4.2 Computation of Euclidean Distance Transform

To segment the space time shape, the 3D distance transform (P.F. Felzenszwalb and D.P. Huttenlocher, 2004) based on the Euclidean distance is computed. This transformation assigns to a interior voxel a value which is proportional to the Euclidean distance between this voxel and the nearest boundary voxel. The computation involves the use of a 3-pass algorithm where each pass is associated with a raster scan of the entire space time shape in a particular dimension using a 1D mask.

The minimum distance calculation is done by finding the local minima of the lower envelope of the set of parabolas where each parabola is defined on the basis of the Euclidean distance between two points (P.F. Felzenszwalb and D.P. Huttenlocher, 2004). The intermediate distance transform values computed in the first pass is based directly on the Euclidean distance. In the next two passes, the distance transform values are computed from the set of parabolas defined on the boundary voxels in the respective dimension. This type of distance transform is given by

\[ D_f(p) = \min_{q \in B} \left( (p - q)^2 + f(q) \right) \]  

where \( p \) is a non-boundary point, \( q \) is a boundary point, \( B \) is the boundary and \( f(q) \) is the value of the distance measure between points \( p \) and \( q \). It is seen that for every \( q \in B \), the distance transform is bounded by the parabola rooted at \((q, f(q))\). In short, the distance transform value at point \( p \) is the minima of the lower envelope of the parabolas formed from every boundary point \( q \). The distance transformation of the space time shape is shown in Figure 4. It is seen that the area covered by the torso part of the body has higher values than the area covered by the limbs. By varying the aspect ratio, the different axes \( x, y \) and \( t \) will have different emphasis on the computed distance transform.

4.3 Segmentation of the 3D Space-time Shape

Human actions are distinguished from the variation of the silhouette and these variations are more along the limbs than in the torso. So, a better representation of the space time shape is required which emphasizes fast moving parts so that the features extracted gives the necessary variation to represent the action. Thus, a normalized gradient of the distance transform is used and, as shown in Figure 5, the fast moving parts such as the limbs have higher values compared to the torso region. The gradient of the space time shape \( \phi(x,y,t) \) (M.Blank et al., 2005) is defined as

\[ \phi(x,y,t) = U(x,y,t) + K_1 \frac{\partial^2 U}{\partial x^2} + K_2 \frac{\partial^2 U}{\partial y^2} + K_3 \frac{\partial^2 U}{\partial t^2} \]  

where \( U(x,y,t) \) is the distance transformed space time shape, \( K_i \) is the weight added to the derivative taken along the \( i^{th} \) axis. The weights associated with the
gradients along each of the axes are usually kept the same. It is seen that the proper variation occurs where the time axis has more emphasis. The fast moving parts in this case being the hands and legs have high values, the region surrounding the torso which are not so fast moving have moderate values while the torso region which moves very slowly with respect to the limbs have very low values. Moreover this representation also contains concatenation of silhouettes from the previous frame onto the current frame due to the gradient and so, the time nature is emphasized in a single frame of the space time shape. In short, this representation of the space time shape is tuned more towards the time variation where this variation is directly related to the action being performed. The normalized gradient \( L(x, y, t) \) is given by

\[
L(x, y, t) = \frac{\log(\phi(x, y, t))}{\max_{(x,y,t) \in S} \phi(x, y, t)}
\]  

\( \text{Figure 7: R-Transform Feature Set of the jumping jack and the walk actions at a finest level.} \)

This normalized gradient is used to segment the space time shape into multiple levels where at each level, the features corresponding to the silhouette variations in a frame are extracted. The standard deviation of \( L(x, y, t) \) is computed to define the interval between adjacent levels. The interval is defined by \( s = \text{StdDev} / \text{Scale} \) where StdDev is the standard deviation and Scale is the factor which is usually taken as 4. The minimum value is taken to be zero and the threshold for each level is computed as \( Th = (p - 1) \times s \) where \( p \) refers to the level. For a \( K \) level segmentation, \( p \) varies from 1 to \( K \). An illustration of 8-level segmentation of a space time shape for different frames are shown in Figure 6. The segmentation is done on each frame using the values of the normalized gradient and from each level, a particular set of features are extracted. In the next section, the type of features extracted from the space time shape will be discussed.

4.4 Extraction of Features

There are two sets of features which are extracted from the segmented space time shape. One is the set of translation invariant R-Transform features obtained at each level and the other is the R-Translation vectors which are extracted at the coarsest level of the space time shape. The R-Transform describes the 2D shape in a frame at a certain level. The set of R-Transforms taken across the frames of the space time shape at
each level gives the posture variations corresponding to a particular action. The R-Translation vector taken at the coarsest level emphasizes the translatory variation of the entire silhouette across the frames of the space-time shape while reducing the emphasis on the posture variations.

### 4.4.1 R-Transform Feature Set

The R-Transform feature set is the set of elements where each element is given by

$$R_{kj}(\alpha) = \int_{-\infty}^{\infty} T_{kj}^2(s, \alpha) ds$$

(5)

where $T_{kj}(s, \alpha)$ is the 2D Radon transform of the frame $k$ of the space-time shape at level $l$ and $\alpha \in [0, \pi]$ is the angle of inclination of the line on which the silhouette in the frame is projected on (S.Tabbone et al., 2006). For a space-time shape containing $K$ frames and for $L$ number of levels, the R-Transform feature set is a 3D matrix of size $L \times M \times K$ where $M$ is the number of angles on which the projection is taken. Typically, $M$ is taken as 180. The surface plot for the R-Transform feature set for a single level is shown in Figure 7. This gives the posture variations of the silhouette across the frames and these differ from action to action and are independent of the person performing it. This is due to the fact that the R-Transform is scale and translation invariant where scale invariance removes the size variations in the persons performing the action and the variations captured are only due to the change of shape. Moreover, being translation invariant, the features are also independent of the position of the person performing the action.

### 4.4.2 R-Translation Vector Set

The R-Translation feature set gives the variations of the silhouette shape across the frames but removes the variation caused due to the translation of the shape. Therefore, to distinguish between the actions which have large translatory motions such as walk and run actions from those which have very little translatory motion such as single hand wave action, another set of features should be extracted which gives the translatory variation while minimizing the time variation of the shape. This type of feature is known as the R-Translation vector, the silhouette in every frame of the space-time shape is shifted with respect to the position of the silhouette in the first frame. The R-Translation vector is then extracted from the modified silhouettes and the variation in this vector across the frames gives the translation of the silhouette. The set of R-Translation vectors extracted from the space-time shape is a matrix of size $K \times M$ where $K$ is the number of frames and $M$ refers to twice the maximum distance of the projection line from the centroid of the silhouette. At every frame $k$, Figure 8 shows a Gaussian-like function having a peak at $s = M/2$ and these Gaussian-like functions do not vary much across the frames for the jumping jack action but for the walk action, there is considerable variation. This shows that the jumping jack action has less translatory motion than the walk action. The small variations that occur in the R-Translation vectors of the jumping jack is due to the posture variations but unlike the R-Transform feature set, the type of variations have less emphasis in the R-Translation vector.

### 5 SIMULATION AND RESULTS

The implementation of the algorithm are done using MATLAB and OPENCV library by calling the necessary functions. The extraction of the silhouettes is done in C++ using OPENCV (G.Bradski and A.Kaehler, 2008) while the rest of the algorithm such as the extraction of R-Translation and R-Transform features is done in the MATLAB environment. The training and the testing is done using the Weizmann action dataset which consists of 90 low-resolution video sequences each having a single person performing a particular action. Each video sequence is taken at 50 fps with a frame size of $180 \times 144$ and the dataset contains 10 different action classes. Space-time shapes are extracted from each of the video sequences by using a window along the time axis where this window is of a pre-defined length. The training and the testing data set thus consists of the space-time shapes extracted from each of the video sequences in the database. For evaluation of the algorithm, a variation of the “leave-one-out” procedure (M.Blank et al., 2005) is used where to test a video sequence, the space-time shapes corresponding to that particular video sequence is taken as the testing data while the training data set is the set of space-time shapes extracted from the sequences excluding the test sequence. Classification of the test set is done by taking each test space-time shape independently and by
comparing the features extracted from it with those extracted from the training space time shapes, the individual test space time shape is classified. The comparison is done using the nearest neighbour rule (C.M.Bishop, 2006) by computing the Euclidean distance between the features. Once the closest training space time shape is identified, its class is noted and the test space time shape is classified under this particular class. The number of test space time shapes classified correctly for each class are noted and this is put up in the form of the confusion matrix. The confusion matrix showing the action recognition rates for the proposed algorithm are shown in Table 1.

The algorithm is also shown to be somewhat consistent with the change in the window size used for extracting the space time shape and the overlap between consecutive shapes. Simulations were done with 6 different sets of (length,overlap) of space time shape - (6,3), (8,4), (10,5), (12,6), (14,7) and (16,8) and the recognition rates for each action achieved with each of the sets is shown in Figure 10. By performing the evaluation with different sets of the window size and overlap, we are inturn evaluating the variation caused due to the speed of the action. If we assume that for a space time shape, we have a fixed start frame, then, by varying the window size, the end frames will differ. This is the same effect as capturing the same action with the same window size but both actions performed at two different speeds. As mentioned before, there is not much variation in the action accuracies for each action except the case of the skip where the accuracy drops to a slightly lower value. As long as the variation in the speed of the action is within a certain limit, the algorithm is consistent with the recognition accuracy.

It can be seen that the accuracy for each action is fairly good enough at around 90 – 95% with some actions having an average accuracy of 88%. But one particular action, the “skip” action gets an accuracy of around 60 – 65%. The impact of this action when computing the overall accuracy achieved with this algorithm is shown in Figure 9.

It is seen that without including the skip action, the algorithm achieves a very good overall accuracy of around 93 – 95% accuracy. The inclusion of the “skip” action reduces the overall accuracy to 90 – 93%. But even with the “skip” action, the overall accuracy is fairly good enough. This reason for the “skip” action to have a poor accuracy when compared to other actions is due to the fact that some of the “skip” space time shapes are qualitatively similar to the “walk” and “run” space time shapes and thus, they get misclassified under the “walk” and “run” actions. The features extracted capture the more global variations of a space time shape and are not able to fully distinguish between the variations in the “skip” to that of the “walk” and “run” space time shapes. One possible way of improving the distinguishability of these features is to extract another subset of features which are more localised and which can provide more discrimination between the space time shapes.

The confusion matrices for the algorithm which use the poisson equation’s based shape descriptor is

Figure 11: Comparison of overall accuracies achieved with the different shape descriptors used in the proposed action recognition framework without including the “skip” action.

given in Table 2. As seen, the algorithm using the Poisson’s equation based shape descriptor gives better accuracy results for some actions especially the “skip” action. This is because the features extracted are localized within the space time shape and thus are able to fully distinguish between the “skip” and “walk” shapes. But, the proposed algorithm attains comparable results with the other actions some actions attaining better accuracy with the proposed one. When compared to other shape descriptors, the proposed algorithm uses a combination of shape descriptors which brings out more time variations relating to the action. This is illustrated in where the shape descriptor used in the proposed algorithm is compared with other shape descriptors. As shown, the shape descriptor used in the proposed action recognition framework has much better overall accuracy than when achieved with using only the 2D shape descriptors to capture the posture variations.

6 CONCLUSIONS

The algorithm proposed in this paper have used the concept of a multi-level representation of a 3D shape for action classification. An action has been considered as a space time shape or a 3D shape and a multi-level representation using the gradient of the 3D Euclidean distance transform and the Radon transform have been used from where the action features have been extracted. Silhouettes from a video sequence containing a particular action have been concatenated to form the space time shape representing that action. Action features were extracted from each level of the representation and these features concatenated as a single feature was used in a nearest neighbour classifier for recognition.

The evaluation of the algorithm was performed by comparing the accuracies attained with different shape descriptors in the proposed algorithm and the results obtained showed higher accuracy rates for the combination of the shape descriptors. Further comparison has been done with another algorithm proposed in (M.Blank et al., 2005) and the results showed comparable recognition accuracies for some actions with some actions having better accuracies with the proposed one. The accuracies were also computed for different shape time shape lengths and overlap and showed that the algorithm was almost consistent with the variation in the length of the space time shape. However, the algorithm has not been evaluated for the variation in the accuracy of a particular action due to the change in the frame rate as the database used for evaluation is limited and contains only sequences captured at a constant frame rate.

Although the average accuracies were high, the accuracy for one particular action obtained by the proposed algorithm is low as the features extracted from the space time shape corresponding to this action cannot be discriminated from those of similar actions. Future work will involve extraction of weights from the action features which corresponds to its variation and then, use a learning based methodology to classify them.
