Abstract

We propose a new regression method to evaluate the impact of changes in the distribution of the explanatory variables on quantiles of the unconditional (marginal) distribution of an outcome variable. The proposed method consists of running a regression of the (recentered) influence function (RIF) of the unconditional quantile on the explanatory variables. The influence function, a widely used tool in robust estimation, is easily computed for quantiles, as well as for other distributional statistics. Our approach, thus, can be readily generalized to other distributional statistics.

KEYWORDS: Influence Functions, Unconditional Quantile, Quantile Regressions.

1.   INTRODUCTION

In this paper, we propose a new computationally simple regression method to estimate the impact of changing the distribution of explanatory variables, X, on the marginal quantiles of the outcome variable, Y, or other functional of the marginal distribution of Y. The method consists of running a regression of a transformation—the (recentered) influence function defined below—of the outcome variable on the explanatory variables. To distinguish our approach from commonly used *conditional* quantile regressions (Koenker and Bassett, 1978; Koenker, 2005), we call our regression method an *unconditional quantile regression*.[1]

Empirical researchers are often interested in changes in the quantiles, denoted q_τ, of the marginal (unconditional) distribution, $F_Y(y)$. For example, we may want to estimate the direct effect $\mathrm{d}q_\tau(p)/\mathrm{d}p$ of increasing the proportion of unionized workers, $p = \Pr[X = 1]$, on the τth quantile of the distribution of wages, where $X = 1$ if the worker is unionized, and $X = 0$ otherwise. In the case of the mean μ, the coefficient β of a standard regression of Y on X is a measure of the impact of increasing the proportion of unionized worker on the mean wage, $\mathrm{d}\mu(p)/\mathrm{d}p$. As is well known, the same coefficient β can also be interpreted as an impact on the conditional mean.[2] Unfortunately, the coefficient β_τ from a single conditional quantile regression, $\beta_\tau = F_Y^{-1}(\tau|X = 1) - F_Y^{-1}(\tau|X = 0)$, is generally different from $\mathrm{d}q_\tau(p)/\mathrm{d}p = (\Pr[Y > q_\tau|X = 1] - \Pr[Y > q_\tau|X = 0])/f_Y(q_\tau)$, the effect of increasing the proportion of unionized workers on the τth quantile of the unconditional distribution of Y.[3] A new approach is therefore needed to provide practitioners with an easy way to compute $\mathrm{d}q_\tau(p)/\mathrm{d}p$, especially when X is not univariate and binary as in the above example.

Our approach builds upon the concept of the influence function, a widely used tool in the robust estimation of statistical or econometric models. As its name suggests, the influence function $\mathrm{IF}(Y; \nu, F_Y)$ of a distributional statistic, $\nu(F_Y)$, represents the influence of an individual observation on that distributional statistic. Adding back the statistic $\nu(F_Y)$ to the influence function yields what we call the *Recentered Influence*

---

[1] The "unconditional quantiles" are the quantiles of the marginal distribution of the outcome variable Y. Using "marginal" instead of "unconditional" would be confusing, however, since we also use the word "marginal" to refer to the impact of small changes in covariates (marginal effects).

[2] The conditional mean interpretation is the wage change that a worker would expect when her union status changes from non-unionized to unionized, or $\beta = E(Y|X = 1) - E(Y|X = 0)$. Since the unconditional mean is $\mu(p) = pE(Y|X = 1) + (1 - p)E(Y|X = 0)$, it follows that $\mathrm{d}\mu(p)/\mathrm{d}p = E(Y|X = 1) - E(Y|X = 0) = \beta$.

[3] The expression for $\mathrm{d}q_\tau(p)/\mathrm{d}p$ is obtained by implicit differentiation applied to $F_Y(q_\tau) = p \cdot (\Pr[Y \leq q_\tau|X = 1] - \Pr[Y \leq q_\tau|X = 0]) + \Pr[Y \leq q_\tau|X = 0]$.

Function (RIF). One convenient feature of the RIF is that its expectation is equal to $\nu\left(F_Y\right)$.[4] Because influence functions can be computed for most distributional statistics, our method easily extends to other choices of ν beyond quantiles, such as the variance, the Gini coefficient and other commonly used inequality measures.[5]

For the τth quantile, the influence function $\text{IF}\left(Y;q_\tau,F_Y\right)$ is known to be equal to $\left(\tau-\mathbb{1}\left\{Y\le q_\tau\right\}\right)/f_Y\left(q_\tau\right)$. As a result, $\text{RIF}\left(Y;q_\tau,F_Y\right)$ is simply equal to $q_\tau+\text{IF}\left(Y;q_\tau,F_Y\right)$. We call the conditional expectation of the $\text{RIF}\left(Y;\nu,F_Y\right)$ modeled as a function of the explanatory variables, $E\left[\text{RIF}\left(Y;\nu,F_Y\right)|X\right]=m_\nu(X)$, the RIF-*regression model*.[6] In the case of quantiles, $E\left[\text{RIF}\left(Y;q_\tau,F_Y\right)|X\right]=m_\tau(X)$ can be viewed as an *unconditional quantile regression*. We show that the average derivative of the unconditional quantile regression, $E\left[m'_\tau(X)\right]$, corresponds to the marginal effect on the unconditional quantile of a small location shift in the distribution of covariates, holding everything else constant.

Our proposed approach can be easily implemented as an OLS regression. In the case of quantiles, the dependent variable in the regression is $\text{RIF}\left(Y;q_\tau,F_Y\right)=q_\tau+\left(\tau-\mathbb{1}\left\{Y\le q_\tau\right\}\right)/f_Y\left(q_\tau\right)$. It is easily computed by estimating the sample quantile, q_τ, estimating the density $f_Y\left(q_\tau\right)$ at that point q_τ using kernel (or other) methods, and forming a dummy variable, $\mathbb{1}\left\{Y\le q_\tau\right\}$, indicating whether the value of the outcome variable is below q_τ. Then we can simply run an OLS regression of this new dependent variable on the covariates, although we suggest more sophisticated estimation methods in Section 3.

We view our approach as an important complement to the literature concerned with the estimation of quantile functions. However, unlike Imbens and Newey (2002), Chesher (2003), and, Florens, Heckman, Meghir, and Vytlacil (2003), who consider the identification of structural functions defined from conditional quantile restrictions in the presence of endogenous regressors, our approach is concerned solely with parameters that capture changes in unconditional quantiles in the presence of exogenous regressors.

The structure of the paper is as follows. In the next section, we define the key object of interest, the "unconditional quantile partial effect" (UQPE) and show how RIF-regressions for the quantile can be used to estimate the UQPE. We also link this parameter to the structural parameters of a general model and the conditional quan-

---

[4]Such property is important in some situations, although for the marginal effects we are interested in this paper the recentering is not fundamental. In Firpo, Fortin and Lemieux (2007b), the recentering is useful because it allows us to identify the intercept and performs Oaxaca-type decomposition at various quantiles.

[5]See Firpo, Fortin and Lemieux (2007b) for such regressions on the variance and Gini.

[6]In the case of the mean, since the RIF is simply the outcome variable, Y, a regression of $\text{RIF}\left(Y;\mu\right)$ on X is the same as an OLS regression of Y on X.

tile partial effects (CQPE). The estimation issues are addressed in Section 3. Section 4 presents an empirical application of our method, that illustrates well the difference between our method and conditional quantiles regressions. We conclude in Section 5.

2. Unconditional Partial Effects

2.1. General Concepts

We assume that Y is observed in the presence of covariates X, so that Y and X have a joint distribution, $F_{Y,X}(\cdot, \cdot) : \mathbb{R} \times \mathcal{X} \rightarrow [0,1]$, and $\mathcal{X} \subset \mathbb{R}^k$ is the support of X. By analogy with a standard regression coefficient, our object of interest is the effect of a small increase in the location of the distribution of the explanatory variable X on the τth quantile of the unconditional distribution of Y. We represent this small location shift in the distribution of X in terms of the counterfactual distribution, $G_X(x)$. By definition, the unconditional (marginal) distribution function of Y can be written as

$$(1) \quad F_Y(y) = \int F_{Y|X}(y|X = x) \cdot \mathrm{d}F_X(x).$$

Under the assumption that the conditional distribution $F_{Y|X}(\cdot)$ is unaffected by this small manipulation of the distribution of X, a counterfactual distribution of Y, G_Y^*, can be obtained by replacing $F_X(x)$ with $G_X(x)$:[7]

$$(2) \quad G_Y^*(y) \equiv \int F_{Y|X}(y|X = x) \cdot \mathrm{d}G_X(x).$$

Our regression method builds on some elementary properties of the influence function, a measure introduced by Hampel (1968, 1974) to study the infinitesimal behavior of real-valued functionals $\nu(F_Y)$, where $\nu : \mathcal{F}_\nu \rightarrow \mathbb{R}$, and where $\mathcal{F}_\nu$ is a class of distribution functions such that $F_Y \in \mathcal{F}_\nu$ if $|\nu(F)| < +\infty$. Let G_Y be another distribution in the same class. Let $F_{Y,t \cdot G_Y} \in \mathcal{F}_\nu$ represent the mixing distribution, which is t away from F_Y in the direction of the probability distribution G_Y, $F_{Y,t \cdot G_Y} = (1 - t) \cdot F_Y + t \cdot G_Y = t \cdot (G_Y - F_Y) + F_Y$, where $0 \leq t \leq 1$. The directional derivative of ν in the direction of the distribution G_Y can be written as:

$$(3) \quad \lim_{t \downarrow 0} \frac{\nu(F_{Y,t \cdot G_Y}) - \nu(F_Y)}{t} = \frac{\partial \nu(F_{Y,t \cdot G_Y})}{\partial t}\Big|_{t=0} = \int \mathrm{IF}(y; \nu, F_Y) \cdot \mathrm{d}(G_Y - F_Y)(y).$$

---

[7]Instead of assuming a constant conditional distribution $F_{Y|X}(\cdot|\cdot)$, we could allow the conditional distributions to vary as long as they converge as the marginal distributions of X converge to one another.

where $\text{IF}(y; \nu, F_Y) = \partial \nu \left(F_{Y, t \cdot \Delta_y} \right) / \partial t |_{t=0}$, with Δ_y denoting the probability measure that puts mass 1 at the value y. The von Mises (1947) linear approximation of the functional $\nu \left(F_{Y, t \cdot G_Y} \right)$ is

$$\nu \left(F_{Y, t \cdot G_Y} \right) = \nu(F_Y) + t \cdot \int \text{IF}(y; \nu, F_Y) \cdot \mathrm{d} \left(G_Y - F_Y \right)(y) + r\left(t; \nu; G_Y, F_Y \right),$$

where $r\left(t; \nu; G_Y, F_Y \right)$ is a remainder term. We define the *Recentered Influence Function* (RIF) as the leading terms of the above expansion for the particular case where $G_Y = \Delta_y$ and $t = 1$. Since $\int \text{IF}(y; \nu, F_Y) \cdot \mathrm{d}F_Y(y) = 0$ by definition, it follows that

$$\text{RIF}(y; \nu, F_Y) = \nu(F_Y) + \int \text{IF}(s; \nu, F_Y) \cdot \mathrm{d}\Delta_y(s) = \nu(F_Y) + \text{IF}(y; \nu, F_Y).$$

Finally, note that the last equality in equation (3) also holds for $\text{RIF}(y; \nu, F_Y)$.

In the presence of covariates X, we can use the law of iterated expectations to express $\nu(F_Y)$ in terms of the conditional expectation of $\text{RIF}(y; \nu, F_Y)$ given X,

$$(4) \ \nu(F_Y) = \int \text{RIF}(y; \nu, F_Y) \cdot \mathrm{d}F_Y(y) = \int \int \text{RIF}(y; \nu, F_Y) \cdot \mathrm{d}F_{Y|X}\left(y|X=x\right) \cdot \mathrm{d}F_X(x),$$

$$= \int E\left[\text{RIF}(Y; \nu, F_Y)|X=x\right] \cdot \mathrm{d}F_X(x),$$

where the first equality follows from the fact that the influence function integrates to zero, and the second equality comes from substituting in equation (1).

Equation (4) shows that when we are interested in the impact of covariates on a specific distributional statistic $\nu(F_Y)$ such as a quantile, we simply need to integrate over $E\left[\text{RIF}(Y; \nu, F_Y)|X\right]$, which is easily done using regression methods. By contrast, in equation (1) we need to integrate over the whole conditional distribution $F_{Y|X}\left(y|X=x\right)$, which is in general more difficult to estimate.[8]

We now state our main result on how the impact of a marginal change in the distribution of X on $\nu(F_Y)$ can be obtained using the conditional expectation of the $\text{RIF}(Y; \nu, F_Y)$. Note that all proofs are provided in the appendix.

---

[8]Most other approaches, such as the conditional quantile regression method of Machado and Mata (2005), have essentially proposed to estimate and integrate the whole conditional distribution, $F_{Y|X}\left(y|X=x\right)$ over a new distribution G_X of X to obtain the counterfactual unconditional distribution of Y. See also Albrecht, Björklund and Vroman (2003) and Melly (2005). By contrast, we show in Section 3 that our approach requires estimating the conditional distribution $F_{Y|X}\left(y|X=x\right) = \Pr\left[Y > y|X=x\right]$ only at one point of the distribution. Note that these approaches do not generate a marginal effect parameter, but instead a total effect of changes in the distribution of X on selected features (e.g. quantiles) of the unconditional distribution of Y.

THEOREM 1 [***Marginal Effect of a Change in the Distribution of X***]: *Suppose we can induce a small perturbation in the distribution of covariates, from F_X in the direction of G_X, maintaining the conditional distribution of Y given X unaffected. The marginal effect of this distributional change on the functional $\nu(F_Y)$ is given by integrating up the conditional expectation of the (recentered) influence function with respect to the changes in distribution of the covariates $d(G_X - F_X)$*

$$\frac{\partial \nu\left(F_{Y,t \cdot G_Y^*}\right)}{\partial t}\Big|_{t=0} = \int E\left[\mathrm{RIF}(Y;\nu,F_Y)|X=x\right] \cdot d\left(G_X - F_X\right)(x)$$

where $F_{Y,t \cdot G_Y^*} = (1-t) \cdot F_Y + t \cdot G_Y^*$.

We next consider a particular change, a small location shift t, in the distribution of covariates X. Let X_j be a continuous covariate in the vector X, where $1 \leq j \leq k$. The new distribution G_X will be the distribution of a random $k \times 1$ vector Z, where $Z_l = X_l$ for $l \neq j$ and $l = 1,\ldots,k$, and $Z_j = X_j + t$. In this special case, let $\alpha_j(\nu)$ denote the partial effect of a small change in the distribution of covariates from F_X to G_X on the functional $\nu(F_Y)$. Collecting all j-entries, we construct the $k \times 1$ vector $\alpha(\nu) = [\alpha_j(\nu)]_{j=1}^k$. We can write the unconditional partial effect $\alpha(\nu)$ as an average derivative.

COROLLARY 1 [***Unconditional Partial Effect***]: *Assume that $d\mathcal{X}$, the boundary of the support $\mathcal{X}$ of X, is such that if $x \in d\mathcal{X}$, then $f_X(x) = 0$. Then, the vector $\alpha(\nu)$ of partial effects of small location shifts in the distribution of a continuous covariate X on $\nu(F_Y)$ can be written using the following vector of average derivatives:*[9]

$$(5) \quad \alpha(\nu) = \int \frac{dE\left[\mathrm{RIF}(Y;\nu)|X=x\right]}{dx} \cdot dF(x).$$

2.2.   The Case of Quantiles

Turning to the specific case of quantiles, consider the τth-quantile, $q_\tau = \nu_\tau(F_Y) = \inf_q \{q : \ F_Y(q) \geq \tau\}$. It follows from the definition of the influence function that

$$\mathrm{RIF}(y;q_\tau) = q_\tau + \mathrm{IF}(y;q_\tau) = q_\tau + \frac{\tau - \mathbb{I}\{y \leq q_\tau\}}{f_Y(q_\tau)} = c_{1,\tau} \cdot \mathbb{I}\{y > q_\tau\} + c_{2,\tau}.$$

where $c_{1,\tau} = 1/f_Y(q_\tau)$, $c_{2,\tau} = q_\tau - c_{1,\tau} \cdot (1-\tau)$, and $f_Y(q_\tau)$ is the density of Y evaluated at q_τ. Thus

$$E\left[\mathrm{RIF}(Y;q_\tau)|X=x\right] = c_{1,\tau} \cdot \Pr\left[Y > q_\tau|X=x\right] + c_{2,\tau}.$$

---

[9]The expression $dE\left[\mathrm{RIF}(Y;\nu)|X=x\right]/dx$ is the k-vector of partial derivatives $\left[\partial E\left[\mathrm{RIF}(Y;\nu)|X=x\right]/\partial x_j\right]_{j=1}^k$.

5

From equation (5) the unconditional partial effect, that we denote $\alpha(\tau)$ in the case of the τth-quantile, simplifies to

$$(6) \quad \alpha(\tau) = \frac{\partial \nu_\tau \left(F_{Y,t \cdot G_Y^*} \right)}{\partial t} \Big|_{t=0} = c_{1,\tau} \cdot \int \frac{d \Pr\left[Y > q_\tau | X = x \right]}{dx} \cdot dF_X(x)$$

where the last term is the average marginal effect from the probability response model $\Pr\left[Y > q_\tau | X \right]$. We call the parameter $\alpha(\tau) = E\left[dE\left[\text{RIF}(Y, q_\tau) | X \right] / dx \right]$ the *unconditional quantile partial effect* (UQPE), by analogy with Wooldridge (2004) unconditional average partial effect (UAPE), which is defined as $E\left[dE\left[Y | X \right] / dx \right]$.[10]

Our next result provides an interpretation of the UQPE in terms of a general structural model, $Y = h(X, \varepsilon)$, where the unknown mapping $h(\cdot, \cdot)$ is invertible on the second argument, and ε is an unobservable determinant of the outcome variable Y. We also show that the UQPE can be written as a weighted average of a family of conditional quantile partial effects (CQPE), which is the effect of a small change of X on the conditional quantile of Y,

$$CQPE(\tau, x) = \frac{\partial Q_\tau \left[h(X, \varepsilon) | X = x \right]}{\partial x} = \frac{\partial h(x, Q_\tau[\varepsilon])}{\partial x}.$$

where $Q_\tau\left[Y | X = x \right] \equiv \inf_q \left\{ q : F_{Y|X}(q|x) \geq \tau \right\}$ is the conditional quantile operator. The last term of the above equation uses the unconditional form for $Q_\tau[\varepsilon]$ as we consider here, for the sake of simplicity and comparability between CQPE and UQPE, the case where ε and X are independent.[11]

In a linear model, $Y = h(X, \varepsilon) = X^\intercal \beta + \varepsilon$, both the UQPE and the CQPE are trivially equal to the parameter β_j of the structural form for any quantile. While this specific result does not generalize beyond the linear model, useful connections can still be drawn between UQPE and the underlying structural form, and between UQPE and CQPE. To establish these connections, we define three auxiliary functions. The first function, $\omega_\tau : \mathcal{X} \to \mathbb{R}^+$, is a weighting function defined as the ratio between the conditional density given $X = x$, and the unconditional density: $\omega_\tau(x) \equiv f_{Y|X}(q_\tau | x) / f_Y(q_\tau)$. The second function, $\varepsilon_\tau : \mathcal{X} \to \mathbb{R}$, is the inverse function $h^{-1}(\cdot, q_\tau)$, which shall exist under the assumption that h is strictly monotonic in ε. The third function, $\zeta_\tau : \mathcal{X} \to (0, 1)$, is a "matching" function indicating where the unconditional quantile q_τ falls in the conditional distribution of Y:

$$\zeta_\tau(x) \equiv \left\{ s : Q_s\left[Y | X = x \right] = q_\tau \right\} = F_{Y|X}(q_\tau | X = x).$$

_____

[10]The UAPE is a special case of Corollary 1 for the mean ($\nu = \mu$), where $\alpha(\mu) = E\left[dE\left[Y | X \right] / dx \right]$ since $\text{RIF}(Y, \mu) = y$.

[11]In this setting, the identification of the UQPE requires $F_{\varepsilon | X}$ to be unaffected by changes in the distribution of covariates. The identification of CQPE requires quantile-independence between ε and X, that is, the τ-conditional quantile of ε given X equals the τ-unconditional quantile of ε. Independence between ε and X guarantees, therefore, that both the UQPE and CQPE parameters are identified.

PROPOSITION 1 [**UQPE and the structural form**]:

i) Assuming that the structural form $Y = h(X, \varepsilon)$ *is strictly monotonic in* ε *and that* X *and* ε *are independent, the parameter* $UQPE(\tau)$ *will be:*

$$UQPE(\tau) = E\left[\omega_\tau(X) \cdot \frac{\partial h(X, \varepsilon_\tau(X))}{\partial x}\right]$$

ii) We can also represent $UQPE(\tau)$ *as a weighted average of* $CQPE(\zeta_\tau(x), x)$:

$$UQPE(\tau) = E\left[\omega_\tau(X) \cdot CQPE(\zeta_\tau(X), X)\right].$$

Result (i) of the above proposition shows formally that $UQPE(\tau)$ is equal to a weighted average (over the distribution of X) of the partial derivatives of the structural function. In the simple case of the linear model mentioned above, it follows that $\partial h(X, \varepsilon_\tau(X))/\partial x = \beta$ and $UQPE(\tau) = \beta$ for all τ. More generally, the UQPE will typically depend on τ in non-linear settings. For example, when $h(X, \varepsilon) = \tilde{h}(X^\intercal \beta + \varepsilon)$, where $\tilde{h}$ is differentiable and strictly monotonic, simple algebra yields $UQPE(\tau) = \beta \cdot \tilde{h}'\left(\tilde{h}^{-1}(q_\tau)\right)$, which depends on τ. Finally, note that independence plays a crucial role here. If, instead, we had dropped the independence assumption between ε and X, we would not be able, even in a linear model, to express $UQPE(\tau)$ as a simple function of the structural parameter β.[12]

Result (ii) shows that $UQPE(\tau)$ is a weighted average (over the distribution of X) of a family of $CQPE(\zeta_\tau(X), X)$ at the $\zeta_\tau(X)$, the conditional quantile corresponding to the τth unconditional quantile of the distribution of Y, q_τ. But while the result (ii) of Proposition 1 provides a more structural interpretation of the UQPE, it is not practical from an estimation point of view as it would require estimating h and F_ε, the distribution of ε, using nonparametric methods. As shown below, we propose a simpler way of estimating the UQPE based on the estimation of average marginal effects.

3. ESTIMATION

In this section, we discuss the estimation of $UQPE(\tau)$ using RIF-regressions. Equation (6) shows that three components are involved in the estimation of $UQPE(\tau)$: the quantile, q_τ, the density of the unconditional distribution of Y, that appears in the constant $c_{1,\tau} = 1/f_Y(q_\tau)$, and the average marginal effect, $E\left[d\Pr\left[Y > q_\tau | X\right]/dX\right]$. We discuss the

---

[12]These examples are worked in detail in the working paper version of this article. See Firpo, Fortin and Lemieux (2007a).

estimation of each component in turn, and then briefly address the asymptotic properties of related estimators.

The estimator of the τth population quantile of the marginal distribution of Y is $\widehat{q}_\tau$, the usual τ^{th} sample quantile, which can be represented, as in Koenker and Bassett (1978), as

$$\widehat{q}_\tau = \arg \min_q \sum_{i=1}^N \left(\tau - \mathbb{1}\{Y_i - q \leq 0\} \right) \cdot (Y_i - q).$$

We estimate the density of Y, $\widehat{f}_Y(\cdot)$, using the kernel density estimator,[13]

$$\widehat{f}_Y(\widehat{q}_\tau) = \frac{1}{N \cdot b} \cdot \sum_{i=1}^N \mathcal{K}_Y \left(\frac{Y_i - \widehat{q}_\tau}{b} \right).$$

where $\mathcal{K}_Y(z)$ is a kernel function and b a positive scalar bandwidth.

We suggest three estimation methods for the UQPE based on three ways, among many, of estimating the average marginal effect $E\left[d\Pr\left[Y > q_\tau | X\right]/dX\right]$. As discussed in Firpo, Fortin and Lemieux (2008), the first two estimators will be consistent if we correctly impose functional form restrictions. The third estimator involves a fully nonparametric first stage, and therefore will be consistent quite generally for the average derivative parameter.

The first method estimates the average marginal effect $E\left[d\Pr\left[Y > q_\tau | X\right]/dX\right]$ with an OLS regression, which provides consistent estimates if $\Pr\left[Y > q_\tau | X = x\right]$ is linear in x. This method, that we call RIF-OLS, consists of regressing $\widehat{\text{RIF}}(Y; \widehat{q}_\tau) = \widehat{c}_{1,\tau} \cdot \mathbb{1}\{Y > \widehat{q}_\tau\} + \widehat{c}_{2,\tau}$ on X. The second method uses a logistic regression of $\mathbb{1}\{Y > \widehat{q}_\tau\}$ on X, to estimate the average marginal effect, which is then multiplied by $\widehat{c}_{1,\tau}$. Again, the average marginal effect from this logit model will be consistent if $\Pr\left[Y > q_\tau | X = x\right] = \Lambda\left(x^\intercal \theta_\tau\right)$, where $\Lambda(\cdot)$ is the cdf of a logistic distribution, and θ_τ is a vector of coefficients. We call this method RIF-Logit. In the empirical section, we use these two estimators and find that, in our application, they yield estimates very close to the fully nonparametric estimator.

The last estimation method, called RIF-NP, is based on a nonparametric estimator that does not require any functional form on $\Pr\left[Y > q_\tau | X = x\right]$ to be consistent. We use the method discussed by Newey (1994) and estimate $\Pr\left[Y > q_\tau | X = x\right]$ by polynomial series. As the object of interest is the average of $d\Pr\left[Y > q_\tau | X = x\right]/dx$, once we have a polynomial function that approximates the conditional probability, we can easily take

---

[13]In the empirical section we propose using the Gaussian kernel. The requirements for the kernel and the bandwidth are described Firpo, Fortin and Lemieux (2008). We propose using the kernel density estimator, but other consistent estimators of the density could be used as well.

derivatives of polynomials and average them. As shown by Stoker (1991) for the average derivative case and later formalized in a more general setting by Newey (1994), the choice of the nonparametric estimator for the derivative is not crucial in large samples. Averaging any regular nonparametric estimator with respect to X yields an estimator that converges at the usual parametric rate, and has the same limiting distribution as other estimators based on different nonparametric methods.[14]

We study the asymptotic properties of our estimators in detail in Firpo, Fortin and Lemieux (2008) where we establish the limiting distributions of these estimators, discuss how to estimate their asymptotic variances, and show how to construct test statistics. Three important results from Firpo, Fortin and Lemieux (2008) are summarized here. The first result is that the asymptotic linear expression of each one of the three estimators consists of three components. The first component is associated with uncertainty regarding the density; the second component with the uncertainty regarding the population quantile; and the third component with the average derivative term $E\left[d\Pr\left[Y > q_\tau | X\right]/dX\right]$. The second result states that because the density is nonparametrically estimated by kernel methods, the rate of convergence of the three estimators will be dominated by this slower term. In Firpo, Fortin and Lemieux (2008), we use a higher-order expansion type of argument to allow for the quantile and the average derivative components to be explicitly included. By doing so, we can introduce a refinement in the expression of the asymptotic variance. Finally, the third result is that to test the null hypothesis that $UQPE = 0$, we do not need to estimate the density, as $E\left[d\Pr\left[Y > q_\tau | X\right]/dX\right] = 0 \Leftrightarrow UQPE = 0$. Thus, we can use test statistics that converge at the parametric rate. In this case, the only components contributing to the asymptotic variance are the quantile and the average derivative.

As with standard average marginal effect, we can also estimate the UQPE for a dummy covariate by estimating $E\left[\Pr\left[Y > q_\tau | X = 1\right]\right] - E\left[\Pr\left[Y > q_\tau | X = 0\right]\right]$ instead of $E\left[d\Pr\left[Y > q_\tau | X\right]/dX\right]$ using any of the three methods discussed above. Like in the example of union status mentioned in the introduction, the UQPE, in such cases, represents the impact of a small change in the probability $p = \Pr\left[X = 1\right]$, instead of the small location shift for a continuous covariate considered in Section 2.[15]

---

[14]Nonparametric estimation of $\Pr\left[Y > q_\tau | X = x\right]$ could also be performed by series approximation of the log-odds ratio, which would keep predictions between 0 and 1 (Hirano, Imbens and Ridder (2003)). Note, however, that we are mainly interested in another object, the derivative $d\Pr\left[Y > q_\tau | X = x\right]/dx$, and imposing that the conditional probability lies in the unit interval does not necessarily add much structure to its derivative.

[15]See Firpo, Fortin, and Lemieux(2007a) for more detail.

4. Empirical Application

In this section, we present an empirical application to illustrate how the unconditional quantile regressions work in practice using the three estimators discussed above.[16] We also show how the results compare to standard (conditional) quantile regressions. Our application considers the direct effect of union status on male log wages, which is well known to be different at different points of the wage distribution.[17] We use a large sample of 266,956 observations on U.S. males from the 1983-85 Outgoing Rotation Group (ORG) supplement of the Current Population Survey.[18]

Looking at the impact of union status on log wages illustrates well the difference between conditional and unconditional quantiles regressions. Consider, for example, the effect of union status estimated at the 90th and 10th quantiles. Finding that the effect of unions (for short) estimated using conditional quantile regressions is smaller at the 90th than at the 10th quantile simply means that unions reduce within-group dispersion, where the "group" consists of workers who share the same values of the covariates X (other than union status). This does not mean, however, that increasing the rate of unionization would reduce overall wage dispersion as measured by the difference between the 90th and the 10th quantiles of the unconditional wage dispersion. To answer this question we have to turn to unconditional quantile regressions.

In addition to the within-group wage compression effect captured by conditional quantile regressions, unconditional quantile regression also capture an inequality enhancing between-group effect linked to the fact that unions increase the conditional mean of wages of union workers. This creates a wedge between otherwise comparable union and non-union workers.[19] As a result, unions tend to increase wages for low wage quantiles where both the between- and within- group effects go in the same direction, but can decrease

---

[16] A Stata ado file that implements the RIF-OLS estimator is available on the author's web site: www.econ.ubc.ca/nfortin.

[17] See, for example, Chamberlain (1994) and Card (1996). For simplicity, we maintain the assumption that union coverage status is exogenous. Studies that have used selection models or longitudinal methods to allow the union status to be endogenously determined (e.g. Lemieux, 1998) suggest that the exogeneity assumption only introduces small biases in the estimation.

[18] We start with 1983 because it is the first year in which the ORG supplement asked about union status. The dependent variable is the real log hourly wage for all wage and salary workers, and the explanatory variables include 6 education classes, married, non-white and 9 experience classes. The hourly wage is measured directly for workers paid by the hour, and obtained be dividing usual earnings by usual hours of work for other workers. Other data processing details can be found in Lemieux (2006).

[19] In the case of the variance, it is easy to write down an analytical expression for the between- and within-group effects (see, for example, Card, Lemieux, and Riddell, 2004) and find the conditions under which one effect dominates the other. It is much harder to ascertain, however, whether the between- or the within-group effect tends to dominate at different points of the wage distribution.

wages for high wage quantiles where the between- and within-group effects go in opposite directions.

As a benchmark, Table 1 reports the RIF-OLS estimated coefficients of the log wages model for the 10th, 50th and 90th quantiles. The results (labeled as UQR for unconditional quantile regressions) are compared with standard OLS (conditional mean) estimates, and with standard quantile regressions (CQR) at the corresponding quantiles. For the sake of comparability, we use simple linear specifications for all estimated models. We also show in Figure 1 how the estimated UQPE of unions changes when we use the RIF-Logit and RIF-NP methods instead.

Interestingly, the UQPE of unions first increases from 0.198 at the 10th quantile to 0.349 at the median, before turning negative (-0.137) at the 90th quantile. These findings strongly confirm the point discussed above that unions have different effects at different points of the wage distribution.[20] The conditional quantile regression estimates reported in the corresponding columns show, as in Chamberlain (1994), that unions shift the location of the conditional wage distribution (i.e. positive effect on the median) but also reduce conditional wage dispersion.

The difference between the estimated effect of unions for conditional and unconditional quantile regression estimates is illustrated in more detail in Panel A of Figure 1, which plots both conditional and unconditional quantile regression estimates of union status at 19 different quantiles (from the 5th to the 95th).[21] As indicated in Table 1, the unconditional union effect is highly non-monotonic, while the conditional effect declines monotonically. More precisely, the unconditional effect first increases from about 0.1 at the 5th quantile to about 0.4 at the 35th quantile, before declining and eventually reaching a large negative effect of over -0.2 at the 95th quantile. By contrast, standard (conditional) quantile regression estimates decline almost linearly from about 0.3 at the 5th quantile, to barely more than 0 at the 95th quantile.

At first glance, the fact that the effect of unions is uniformly positive for conditional quantile regressions, but negative above the 80th quantile for unconditional quantile regressions may seem puzzling. Since Proposition 1 states that the UQPE is a weighted average of the CQPEs, for the UQPE to be negative it must be that some of the CQPEs are negative too. Unlike the UQPE, however, the CQPE generally depends on X. For the sake of clarity, in Figure 1 we report the conditional quantile regressions using a highly

---

[20]Note that the effects are very precisely estimated for all specifications, and the R-square's (close to 0.40) are sizeable for cross-sectional data.

[21]Bootstrapped standard errors are provided for both estimates. Analytical standard errors for the UQPE are non-trivial and derived in Firpo, Fortin and Lemieux (2008).

restricted specification where the effect of unions is not allowed to depend on a rich set of other covariates (no interaction terms). When we relax this assumption, we find that conditional quantile regressions estimates are often negative for more "skilled" workers (in high education/high labor market experience cells). However, these negative effects are averaged away by positive effects in the more parsimonious conditional quantile regressions. On the other hand, because the matching function $\zeta_\tau(x)$ from Proposition 1 reassigns some of the negative union effects from the s-conditional quantiles to the τ-unconditional quantiles at the top of the wage distribution, and because the weighting function $\omega_\tau(x)$ puts more weight on these workers, the UQPE becomes negative for workers at the top end of the wage distribution.

Panel B shows that the RIF-OLS and RIF-Logit estimates of the UQPE are very similar, which confirms the "folk wisdom" in empirical work that, in many instances, using a linear probability model or a logit give very similar average marginal effects. More importantly, the figure shows that the RIF-NP estimates are also very similar to the estimates obtained using these two simpler methods.[22] This suggests that, at least for this particular application, using a simple linear specification for the unconditional quantile regressions provides fairly accurate estimates of the UQPE. The small difference between RIF-OLS and RIF-NP estimates stands in sharp contrast with the large differences between the RIF-OLS estimates and the conditional quantile regression estimates in Panel A.

The large differences between the conditional and unconditional quantile regressions results have important implications for understanding recent changes in wage inequality. There is a long tradition in labor economics of attempting to estimate the effect of unionization on the (unconditional) distribution of wages.[23] The unconditional quantile regressions provide a simple and direct way of estimating this effect at all points of the distribution. The estimates reported in Figure 1 show that unionization progressively increases wages in the three lower quintiles of the distribution, peaking around the 35th quantile, and actually reduces wages in the top quintile of the distribution. As a result, the decline in unionization over the last three decades should have contributed to a reduction in wage inequality at the bottom end of the distribution, and to an increase in wage inequality at the top end. This precisely mirrors the actual U-shaped changes

---

[22]The RIF-NP is estimated using a model fully saturated with all possible interactions (up to 432 parameters) of our categorical variables, omitting for each estimated quantile the interactions that would result in perfect predictions. For the RIF-OLS, the figure graphs the estimated coefficients, while for the RIF-Logit and RIF-NP, the average unconditional partial effects are displayed.

[23]See, for example, Card (1996) and DiNardo, Fortin, and Lemieux (1996).

observed in the data.[24] By contrast, conditional quantile regressions results describe a positive but monotonically declining effect of unionization on wages, which fails to account for the observed pattern of changes in the wage distribution.

5. CONCLUSION

In this paper, we propose a new regression method to estimate the effect of explanatory variables on the unconditional quantiles of an outcome variable. The proposed unconditional quantile regression method consists of running a regression of the (recentered) influence function of the unconditional quantile of the outcome variable on the explanatory variables. The influence function is a widely used tool in robust estimation that can easily be computed for each quantile of interest. We show how standard partial effects, that we call unconditional quantile partial effects (UQPE), can be estimated using our regression approach.

Another important advantage of the proposed method is that it can be easily generalized to other distributional statistics such as the Gini, the log variance or the Theil coefficient. Once the recentered influence function for these statistics is computed, all that is required is running a regression of the resulting RIF on the covariates. We discuss in a companion paper (Firpo, Fortin, and Lemieux, 2007b) how our regression method can be used to generalize traditional Oaxaca-Blinder decompositions, devised for means, to other distributional statistics.

Finally, our method can be useful even when the independence assumption is relaxed. However, the interpretation of the identified parameter in terms of its relation to the structural function linking observed and unobserved factors to the dependent variable would change. Yet, the UQPE parameter would still be defined by holding unobserved variables and other components of X fixed when evaluating the marginal effect of changes in the distribution of X_j on a given quantile of the unconditional distribution of Y. Such structural averaged marginal effects can still be useful in practice. We plan to show in future work how our approach can be used when instrumental variables are available for the endogenous covariates, and how consistent estimates of marginal effects can be obtained by adding a control function in the unconditional quantile regressions.

---

6. APPENDIX

Proof of Theorem 1:

The effect on the functional ν of the distribution of Y of an infinitesimal change in the distribution of X from F_X towards G_X is defined as $\partial \nu \left(F_{Y,t \cdot G_Y^*} \right) / \partial t |_{t=0}$. Given that equation (3) also applies to $\mathrm{RIF}(y; \nu)$, it follows that

$$\frac{\partial \nu \left(F_{Y,t \cdot G_Y^*} \right)}{\partial t} |_{t=0} = \int \mathrm{RIF}(y; \nu) \cdot d \left(G_Y^* - F_Y \right)(y).$$

Substituting in equations (1) and (2), and applying the fact that $E[\mathrm{RIF}(Y; \nu)|X = x]$ $= \int_y \mathrm{RIF}(y; \nu) \cdot dF_{Y|X}(y|X = x)$ yields

$$\frac{\partial \nu \left(F_{Y,t \cdot G_Y^*} \right)}{\partial t} |_{t=0} = \int \left(\int \mathrm{RIF}(y; \nu) \cdot dF_{Y|X}(y|X = x) \right) \cdot d \left(G_X - F_X \right)(x)$$

$$= \int E \left[\mathrm{RIF}(Y; \nu)|X = x \right] \cdot d \left(G_X - F_X \right)(x)$$

Q.E.D.

Proof of Corollary 1:

Consider the distribution $\widetilde{G}_X(\cdot; t)$ of the random vector $Z = X + t_j$, where $t_j = t \cdot \mathbf{e}_j$ and $\mathbf{e}_j = [0, \ldots, 0, 1, 0, \ldots, 0]^\intercal$, which is a k-vector of zeros except at the jth-entry which equals one. The density of Z is $\widetilde{g}_X(x; t) = f_X(x - t_j)$.[25] The counterfactual distribution $\widetilde{G}_Y^*(\cdot; t)$ of Y using $F_{Y|X}$ and $\widetilde{G}_X(\cdot; t)$ will be

$$\widetilde{G}_Y^*(y; t) = \int F_{Y|X}(y|x) \cdot f_X(x - t_j) \cdot dx$$

$$= \int F_{Y|X}(y|x) \cdot f_X(x) \cdot dx - t \cdot \int F_{Y|X}(y|x) \cdot \frac{\partial f_X(x)/\partial x_j}{f_X(x)} \cdot f_X(x) \cdot dx + \chi_t$$

$$= F_Y(y) + t \cdot \int F_{Y|X}(y|x) \cdot \mathbf{e}_j^\intercal \cdot l_X(x) \cdot f_X(x) \cdot dx + \chi_t,$$

where the second line is obtained using a first order expansion, where $l_X(x) = -d \ln \left(f_X(x) \right)/dx = -f_X'(x)/f_X(x)$, and $f_X'(x) = [\partial f_X(x)/\partial x_l]_{l=1}^k$ is the k-vector of partial derivatives of $f_X(x)$. Therefore, $\chi_t = O(t^2)$. Now, define

$$g_X(x) = f_X(x) \cdot \left(1 + \mathbf{e}_j^\intercal \cdot l_X(x) \right) \quad \text{and} \quad G_X(x) = \int^x g_X(\xi) \cdot d\xi.$$

---

[25]The density of X is $f_X(\cdot)$, and by definition of densities, $\int^x f_X(\xi) \cdot d\xi = F_X(x)$.

14

By the usual definition of the counterfactual distribution G_Y^* of Y using $F_{Y|X}$ and G_X, we have

$$G_Y^*(y) = \int F_{Y|X}(y|x) \cdot g_X(x) \cdot dx$$

$$= F_Y(y) + \int F_{Y|X}(y|x) \cdot \mathbf{e}_j^\intercal \cdot l_X(x) \cdot f_X(x) \cdot dx.$$

Thus we can write

$$\widetilde{G}_Y^*(y;t) = F_Y(y) + t \cdot (G_Y^*(y) - F_Y(y)) + \chi_t = F_{Y,t \cdot G_Y^*} + \chi_t.$$

Hence,

$$\alpha_j(\nu) \equiv \lim_{t \downarrow 0} \frac{\nu\left(\widetilde{G}_Y^*(\cdot;t)\right) - \nu(F_Y)}{t}$$

$$= \lim_{t \downarrow 0} \left(\frac{\nu\left(F_{Y,t \cdot G_Y^*}\right) - \nu(F_Y)}{t}\right) + \lim_{t \downarrow 0} \left(\frac{\nu\left(\widetilde{G}_Y^*(\cdot;t)\right) - \nu(F_{Y,t \cdot G_Y^*})}{t}\right)$$

$$= \frac{\partial \nu\left(F_{Y,t \cdot G_Y^*}\right)}{\partial t}\Big|_{t=0} + \lim_{t \downarrow 0} \left(\frac{\nu\left(F_{Y,t \cdot G_Y^*} + \chi_t\right) - \nu(F_{Y,t \cdot G_Y^*})}{t}\right)$$

where the last term vanishes

$$\lim_{t \downarrow 0} \left(\frac{\nu\left(F_{Y,t \cdot G_Y^*} + \chi_t\right) - \nu(F_{Y,t \cdot G_Y^*})}{t}\right) = \lim_{t \downarrow 0} \left(\frac{O(\chi_t)}{t}\right) = \lim_{t \downarrow 0} (O(|t|)) = O(1) \cdot \lim_{t \downarrow 0} t.$$

Using Theorem 1, it follows that

$$\alpha_j(\nu) = \frac{\partial \nu\left(F_{Y,t \cdot G_Y^*}\right)}{\partial t}\Big|_{t=0} = \int E\left[\text{RIF}(Y;\nu)|X = x\right] \cdot d(G_X - F_X)(x)$$

$$= \int E\left[\text{RIF}(Y;\nu)|X = x\right] \cdot \mathbf{e}_j^\intercal \cdot l_X(x) \cdot f_X(x) \cdot dx,$$

applying partial integration and using the condition that $f_X(x)$ is zero at the boundary of the support

$$\mathbf{e}_j^\intercal \cdot \int E\left[\text{RIF}(Y;\nu)|X = x\right] \cdot l_X(x) \cdot f_X(x) \cdot dx = \int \mathbf{e}_j^\intercal \cdot \frac{dE\left[\text{RIF}(Y;\nu)|X = x\right]}{dx} \cdot f_X(x) \cdot dx$$

$$= \int \frac{\partial E\left[\text{RIF}(Y;\nu)|X = x\right]}{\partial x_j} \cdot f_X(x) \cdot dx$$

Hence $\alpha_j(\nu) = \int \frac{\partial E\left[\text{RIF}(Y;\nu,F)|X = x\right]}{\partial x_j} \cdot f_X(x) \cdot dx.$

Proof of Proposition 1:

i) Starting from equation (6)

$$UQPE\left(\tau\right) = -\frac{1}{f_Y\left(q_\tau\right)} \cdot \int \frac{d\Pr\left[Y \le q_\tau|X = x\right]}{dx} \cdot dF_X\left(x\right),$$

and assuming that the structural form $Y = h(X, \varepsilon)$ is monotonic in ε, so that $\varepsilon_\tau\left(x\right) = h^{-1}\left(x, q_\tau\right)$, we can write

$$\Pr\left[Y \le q_\tau|X = x\right] = \Pr\left[\varepsilon \le \varepsilon_\tau(X)|X = x\right]$$
$$= F_{\varepsilon|X}\left(\varepsilon_\tau\left(x\right)|x\right) = F_\varepsilon\left(\varepsilon_\tau\left(x\right)\right).$$

Taking the derivative with respect to x, we get

$$d\frac{\Pr\left[Y \le q_\tau|X = x\right]}{dx} = f_\varepsilon\left(\varepsilon_\tau\left(x\right)\right) \cdot \frac{\partial h^{-1}\left(x, q_\tau\right)}{\partial x}.$$

Define $H\left(x, \varepsilon_\tau\left(x\right), q_\tau\right) = h\left(x, \varepsilon_\tau\left(x\right)\right) - q_\tau$, it follows that

$$\frac{\partial h^{-1}\left(x, q_\tau\right)}{\partial x} = \frac{\partial \varepsilon_\tau\left(x\right)}{\partial x} = -\frac{\partial H\left(x, \varepsilon_\tau, q_\tau\right)/\partial x}{\partial H\left(x, \varepsilon_\tau, q_\tau\right)/\partial \varepsilon_\tau}$$
$$= -\frac{\partial h\left(x, \varepsilon_\tau\right)/\partial x}{\partial h\left(x, \varepsilon_\tau\right)/\partial \varepsilon_\tau} = -\frac{\partial h\left(x, \varepsilon_\tau\right)}{\partial x} \cdot \left(\frac{\partial h\left(x, \varepsilon\right)}{\partial \varepsilon}|_{\varepsilon = \varepsilon_\tau}\right)^{-1}.$$

Similarly

$$\frac{\partial h^{-1}\left(x, q_\tau\right)}{\partial q_\tau} = -\frac{\partial H\left(x, \varepsilon_\tau, q_\tau\right)/\partial q_\tau}{\partial H\left(x, \varepsilon_\tau, q_\tau\right)/\partial \varepsilon_\tau} = \left(\frac{\partial h\left(x, \varepsilon\right)}{\partial \varepsilon}|_{\varepsilon = \varepsilon_\tau}\right)^{-1}.$$

Hence:

$$f_{Y|X}\left(q_\tau; x\right) = d\frac{\Pr\left[Y \le q_\tau|X = x\right]}{dq_\tau} = d\frac{F_\varepsilon\left(h^{-1}\left(x, q_\tau\right)\right)}{dq_\tau}$$
$$= f_\varepsilon\left(\varepsilon_\tau\left(x\right)\right) \cdot \frac{\partial h^{-1}\left(x, q_\tau\right)}{\partial q_\tau}$$
$$= \left(\frac{\partial h\left(x, \varepsilon\right)}{\partial \varepsilon}|_{\varepsilon = \varepsilon_\tau}\right)^{-1} \cdot f_\varepsilon\left(\varepsilon_\tau\left(x\right)\right).$$

Substituting in these expressions yields

$$
\begin{aligned}
UQPE\left(\tau\right)= & \ -\left(f_Y\left(q_\tau\right)\right)^{-1}\cdot\int d\frac{\Pr\left[Y\le q_\tau|X=x\right]}{dx}\cdot dF_X\left(x\right)\\
= & \ \left(f_Y\left(q_\tau\right)\right)^{-1}\cdot\int\left(f_\varepsilon\left(\varepsilon_\tau\left(x\right)\right)\cdot\frac{\partial h\left(x,\varepsilon_\tau\right)}{\partial x}\cdot\left(\frac{\partial h\left(x,\varepsilon\right)}{\partial\varepsilon}|_{\varepsilon=\varepsilon_\tau}\right)^{-1}\right)\cdot dF_X\left(x\right)\\
= & \ \left(f_Y\left(q_\tau\right)\right)^{-1}\cdot E\left[f_{Y|X}\left(q_\tau|X\right)\cdot\frac{\partial h\left(X,\varepsilon_\tau\left(X\right)\right)}{\partial x}\right]\\
= & \ E\left[\frac{f_{Y|X}\left(q_\tau|X\right)}{f_Y\left(q_\tau\right)}\cdot\frac{\partial h\left(X,\varepsilon_\tau(X)\right)}{\partial x}\right]\\
= & \ E\left[\omega_\tau\left(X\right)\cdot\frac{\partial h\left(X,\varepsilon_\tau(X)\right)}{\partial x}\right].
\end{aligned}
$$

$$Q.E.D.$$

ii) Let the CQPE can be defined as: $CQPE\left(\tau,x\right)=d\dfrac{Q_\tau\left[Y|X=x\right]}{dx}$

where τ denote the quantile of the conditional distribution: $\tau=\Pr\left[Y\le Q_\tau\left[Y|X=x\right]|X=x\right]$. Since $Y=h(X,\varepsilon)$ is monotonic in ε

$$
\begin{aligned}
\tau= & \ \Pr\left[Y\le Q_\tau\left[Y|X=x\right]|X=x\right]\\
= & \ \Pr\left[\varepsilon\le h^{-1}\left(X,Q_\tau\left[Y|X=x\right]\right)|X=x\right]=F_\varepsilon\left(h^{-1}\left(x,Q_\tau\left[Y|X=x\right]\right)\right).
\end{aligned}
$$

Thus, by the implicit function theorem

$$
\begin{aligned}
CQPE\left(\tau,x\right)= & \ -\frac{f_\varepsilon\left(h^{-1}\left(x,Q_\tau\left[Y|X=x\right]\right)\right)\cdot\partial h^{-1}\left(x,Q_\tau\left[Y|X=x\right]\right)/\partial x}{f_\varepsilon\left(h^{-1}\left(x,Q_\tau\left[Y|X=x\right]\right)\right)\cdot\partial h^{-1}\left(x,q\right)/\partial q|_{q=Q_\tau\left[Y|X=x\right]}}\\
= & \ -\left(-\partial h\left(x,h^{-1}\left(x,Q_\tau\left[Y|X=x\right]\right)\right)/\partial x\right)\\
& \ \cdot\left(\frac{\partial h\left(x,\varepsilon\right)}{\partial\varepsilon}|_{\varepsilon=h^{-1}(x,Q_\tau\left[Y|X=x\right])}\right)^{-1}/\left(\frac{\partial h\left(x,\varepsilon\right)}{\partial\varepsilon}|_{\varepsilon=h^{-1}(x,Q_\tau\left[Y|X=x\right])}\right)^{-1}\\
= & \ \frac{\partial h\left(x,h^{-1}\left(x,Q_\tau\left[Y|X=x\right]\right)\right)}{\partial x}.
\end{aligned}
$$

Using the matching function $\zeta_\tau\left(x\right)\equiv\{s:Q_s\left[Y|X=x\right]=q_\tau\}$, we can write $CQPE\left(s,x\right)$ for the τth conditional quantile at a fixed x ($Q_s\left[Y|X=x\right]$) that equals (matches) the τth

unconditional quantile (q_τ) as:

$$
\begin{aligned}
CQPE\left(s,x\right) &= CQPE\left(\zeta_\tau(x),x\right) \\
&= \frac{\partial h\left(x,h^{-1}\left(x,Q_s\left[Y|X=x\right]\right)\right)}{\partial x} \\
&= \frac{\partial h\left(x,h^{-1}\left(x,q_\tau\right)\right)}{\partial x} = \frac{\partial h\left(X,\varepsilon_\tau(X)\right)}{\partial x}.
\end{aligned}
$$

Therefore

$$
UQPE\left(\tau\right) = E\left[\omega_\tau\left(X\right)\cdot\frac{\partial h\left(X,\varepsilon_\tau(X)\right)}{\partial x}\right] = E\left[\omega_\tau\left(X\right)\cdot CQPE\left(\zeta_\tau(X),X\right)\right].
$$

$$Q.E.D.$$

Note: Robust standard errors (OLS) and bootstrapped standard errors (200 replications) for UQR and CQR in parentheses. All regressions also include a set of dummies for labor market experience categories.
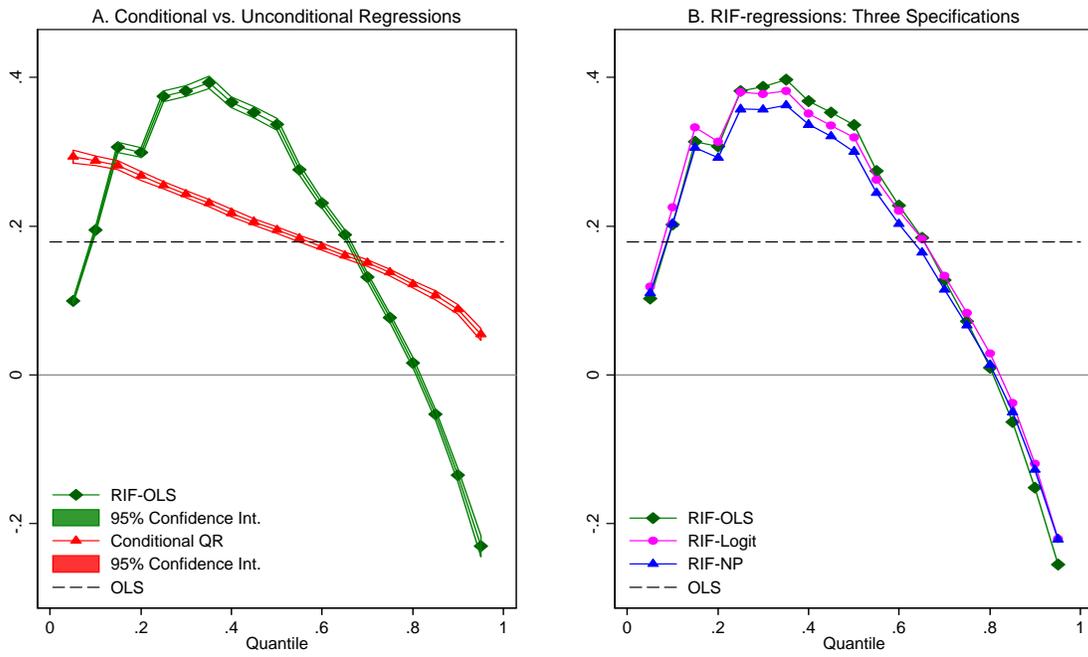

FIGURE 1.—Unconditional and Conditional Quantile Regression Estimates of
the Effect of Union Status

Appendix: Understanding differences in the shape of the conditional and unconditional quantile regressions.

In this appendix, we show empirically the source of the difference between the conditional and unconditional quantile regression coefficients illustrated in Figure 1. For the sake of simplicity, we consider a case where the set of covariates X just consists of the experience and education variables. Since we work with 6 education and 9 experience groups in the paper, this yields a total of 54 experience-education cells. As a further simplification, we divide each of the 54 cells into union and nonunion workers, and compute the average wage for each decile of each of these 108 groups. We use these average wages by deciles as a simple way of smoothing the quantiles of the unconditional wage distribution. For instance, we assume that the average wage of the second decile of the wage distribution is equal to the 15th quantile (the mid-point of the second decile). From this, we directly compute the CQPEs for the 5th, 15th, 25th,…, and 95th quantile of each of the 54 cells by taking the difference between the union and nonunion wage quantiles.

Figure A1 plots the CQPEs as a function of what we call the conditional percentiles of the wage distribution. These conditional percentiles are simply the points mentioned above at which we have evaluated the CQPE (0.05, 0.15, 0.25…, 0.095), and correspond to the values of s in Proposition 1. Each point in Figure A1 is weighted by the proportion of observations in the relevant experience-education cell.

Figure A1 shows considerable heterogeneity in the value of the CQPE at each conditional percentile. On average, the CQPE is similar to the conditional quantile regressions shown in Figure 1. But there is a lot of dispersion in the estimated CQPE and negative values are quite common. As it turns out, cells with a low or negative CQPE tend to be those where workers have high levels of experience and education. This is consistent with the literature on union wage effects where it has been shown that unions have a low or even negative effect among high skill workers.

Proposition 1 states that to go from the CQPEs to the UQPE, we need to use a matching function that maps the unconditional percentile of interest (τ) into the corresponding conditional percentile (s) for each value of X. In practice, we can do so by looking at each observation contained in the conditional deciles used to compute the CQPEs, computing its rank in the overall distribution, and using this average as an estimate of the unconditional percentile τ. Figure A2 plots the CQPEs as a function of the unconditional percentile τ. The inverse U-shaped pattern of results now looks remarkably similar to the figure for the UQPE shown in Figure 1. What happens is that since points with a negative CQPE then to belong to high skill cells, these points tend to be systematically shifted to the right of the graph since they correspond to wage values in the top end of the unconditional wage distribution.
