Part of Special Issue “Eleventh International EISCAT Workshop”

Abstract. Experimental results from three ionospheric HF pumping experiments in overdense E or F regions are summarized. The experiments were conducted by the use of the EISCAT HF Heating facility located near Tromsø, Norway, allowing HF pumping the ionosphere in a near geomagnetic field-aligned direction. Distinctive features related to auroral activations in the course of the experiments are identified. Typical features observed in all experiments are the following: generation of scattered components in dynamic HF radio scatter Doppler spectra; strong increase of ion temperatures T_i and local ionospheric electric field E_0 ; modification of the auroral arc and local spiral-like formation. However, some effects were observed only when the HF pump wave was reflected from the $F2$ layer. Among them are the generation of intense field-aligned ion outflows, and a strong increase in the electron temperature T_e with altitude. A possible scenario for the substorm triggering due to HF pumping into an auroral ionosphere is discussed. The authors present their interpretation of the data as follows. It is suggested that two populations of charged particles are at play. One of them is the runaway population of electrons and ions from the ionosphere caused by the effects of the powerful HF radio wave. The other is the population of electrons that precipitate from the magnetosphere. It is shown that the hydrodynamical equilibrium was disrupted due to the effects of the HF pumping. We estimate that the parallel electric field can reach values of the order of 30 mV/m during substorm triggering.

Key words. Ionosphere (active experiments; ionosphere-magnetosphere interactions). Radio science (nonlinear phenomena).

1 Introduction

The significance of the general class of problems related to the manmade impact on the near-Earth space environment is evident from the results of well-known scientific programs such as TRIGGER, CRRES, CEDAR, and HAARP. Nevertheless, a number of crucial problems still remain unsolved, among them those associated with the modification of the ionosphere-magnetosphere coupling, the possible active role of the ionosphere in magnetospheric dynamics, and the response of the ionosphere-magnetosphere system to artificial perturbations. The controlled injection of powerful radio waves into space from purpose-built ground-based HF radio facilities has proved to be an excellent tool for studying the associated fundamental linear and nonlinear plasma processes and instabilities.

Considerable success has been achieved by the use of the EISCAT HF Heating facility located at auroral latitudes in Tromsø, Norway (see, for example, Stubbe, 1996 (and references therein); Thidé et al., 1982; 1983; Rietveld et al., 1993, 2000; Robinson et al., 1998; Leyser, 2001; Leyser et al., 1989; Isham et al., 1990; 1999; Jones et al., 1984; Honary et al., 1999; Yeoman et al., 1997; Brändström et al., 1999; Eglitis et al., 1998; Blagoveshchenskaya et al., 1998b; Kosch et al., 2000).

It should be noted that in most HF pumping experiments performed hitherto, the plasma physics aspect has, for obvious reasons, dominated. However, taking the distinctive features and behavior of the auroral ionosphere into account, one would expect that the interaction between powerful HF radio waves and the auroral near-Earth space plasma can lead to the generation of specific modification effects not encountered at middle latitudes. As this article will show, this is indeed the case.

Operational modes	Date of experiments

Table 1. Operational modes of the EISCAT HF heating facility during experiments.

A large volume of work has been conducted by many scientists in understanding auroral substorm (see, for example, Akasofu, 1964; Kamide and Baumjohann, 1993; Kan, 1993; Foster, 1995; Lyons, 1996; Sergeev et al. 1996; Rostoker, 1999). Nonetheless, some problems still remain unsolved, among them is the role of internal instabilities in the magnetosphere-ionosphere system leading to substorm triggering, a role of the auroral ionosphere in the substorm process. In this respect HF pumping experiments at auroral latitudes can provide answers to such problems. Experimental results from multi-instrument observations during Tromsø ionospheric modification experiments (Blagoveshchenskaya et al., 2001), make it evident that HF pumping into a sporadic auroral E_s layer in the near field-aligned direction, can lead to a local auroral activation. The results obtained suggest that the energy source for such activations is the interaction between the solar wind and the magnetosphere.

Certain possibilities of HF pumping experiments related to the role of the ionospheric Alfvén resonator (IAR) in auroral phenomena were considered by Trakhtengerts et al. (2000). The theory developed allows for two types of triggering of the Alfvén vortex instability (AVI) in the IAR. The first is the generation of a resonant current in the dynamo region of the ionosphere. Its frequency and spatial scale across the magnetic field should coincide with the eigenfrequency and wavelength of the Alfvén vortex. The second type is based on a non-resonant local variation of the macroscopic electric field that can artificially turn on the AVI in the heated region (Trakhtengerts et al., 2000).

Excitation of Alfvén waves by modulated HF heating of the ionosphere, as well as the stimulated electron precipitation, was detected from the FAST satellite at an altitude of 2550 km above the Tromsø HF heater (Robinson et al., 2000).

In the present paper we invest our efforts on the further research of the ionospheric modification effects in the ionosphere-magnetosphere system caused by powerful HF radio waves. The main attention has been paid to the search for distinctive features related to the modification of the

ionosphere-magnetosphere coupling in the course of three Tromsø HF pumping experiments in the nightside auroral ionosphere. Experimental results from multi-instrument observations in the course of the experiment on 2 October 1998 are examined in detail. In this event, the HF pump wave was reflected from the F2 layer in contrast to other experiments, when the powerful wave was reflected from a sporadic E_s layer. The possible mechanisms responsible for the triggering of local auroral activations due to the effects of powerful HF radio waves are also discussed. The successful resolution of the problem concerning the HF pump wave impact on the ionosphere-magnetosphere coupling that could lead to the triggering of auroral activations requires the following: (1) fundamental studies in several fields and sub-fields, including plasma instabilities and nonlinear phenomena, on the one hand, and environmental magnetospheric physics, on the other; (2) the use of multi-instrument observations, new instruments, methods and observational methodology; (3) the performance of HF pumping experiments under specific geophysical conditions; (4) consistent, repeatable effects needed, that is more events showing the same effect.

Below we present our interpretation of the experimental data obtained in the course of HF ionospheric modification experiments in the nightside auroral ionosphere.

2 Description of the HF pumping experiments

The experiments reported here were carried out by the use of the EISCAT HF Heating facility (Rietveld et al., 1993) located near Tromsø, Norway (geographical coordinates 69.6° N, 19.2° E; magnetic dip angle $I=78^\circ$). We have summarized the experimental findings from such experiments performed in the nightside auroral ionosphere on 16 and 17 February 1996, and 2 October 1998. Notable is that in the course of the experiment on 16 February 1996, two auroral events occurred. A distinctive feature of the experiments is the tilt of the heater antenna beam to the south from zenith of 6° or 12°, thus allowing HF pumping in a near field-aligned direction. The heating phased antenna array No. 2 was used in all experiments. The duration of the heater-on cycles was in all cases 4 or 8 minutes. The operational modes and the main parameters of the HF Heating facility for the experiments are given in Table 1.

The diagnostics of the ionospheric plasma based on effects due to HF pumping comprised multi-instrument observations from bistatic HF Doppler scatter (Blagoveshchenskaya et al., 1998a), the European Incoherent Scatter (EISCAT) UHF radar (Rishbeth and van Eyken, 1993), the digital all-sky imager DASI (Kosch et al., 1998), and the International Monitor for Auroral Geomagnetic Effects (IMAGE) magnetometer network in Scandinavia (Lühr et al., 1998). Additionally, bistatic scatter measurements of HF diagnostic signals were carried out on the London–Tromsø–St. Petersburg path at operational frequencies of 12,095 and 9410 kHz. The diagnostic HF transmitter is located near London (52° N, 0° E). The reception of the diagnostic waves, scattered from

field-aligned irregularities (FAIs) above Tromsø, was made with a Doppler spectral method in St. Petersburg (60° N, 30.5° E) at a great circle distance of ~1200 km from Tromsø. The condition for a bistatic scatter is given by

$$(k_0 \cdot B) = (k_S \cdot B), \quad (1)$$

where k_0 and k_S are the wave vectors of the incident and scattered wave respectively, and B is the vector of the Earth's magnetic field. A general view of the experiment geometry is shown in Fig. 1 of Blagoveshchenskaya et al. (2001). The simulation of bistatic scatter geometry for Tromsø HF pumping experiments is given by Borisova et al., (2002).

The onsets of the activations are the following: 21:21 and 22:41 UT on 16 February 1996; 20:33 UT on 17 February 1996, 19:30 UT on 2 October 1998. The first three activations were observed when the powerful HF radio waves were reflected from the sporadic E_s layers, but the last activation occurred when the HF pump wave was reflected from the $F2$ layer.

In addition to IMAGE magnetometer data, AE , AU , and AL indices of the auroral activity, the PC index from the near pole Vostok magnetic station (Troshichev et al., 1988), the D_{st} index of the magnetic activity, and parameters of the interplanetary magnetic field from the IMP-8 satellite have been used in the analysis of the auroral activations.

The results from the multi-instrument observations during Tromsø HF pumping experiments on 16 and 17 February 1996, when the powerful HF radio wave was reflected from the sporadic E_s layer, were analyzed in detail by Blagoveshchenskaya et al. (2001). Experimental findings from the experiment of 2 October 1998, under the reflection of the HF pump wave from the $F2$ layer of the ionosphere, are given in the next section.

3 Observational results of 2 October 1998

The experiment on 2 October 1998 was conducted during planetary-scale disturbed magnetic conditions. The values of the D_{st} index ranged between -56 and -61 nT. The behavior of the interplanetary magnetic field (IMF) as measured from the IMP-8 satellite is shown in Fig. 1. The top panel in Fig. 1 displays variations of the PC index from the near-pole Vostok station. One can see that the B_z component of the IMF was steadily southward from 16:00 to 22:00 UT.

Ionograms from the Tromsø dynasonde showed that the critical frequencies of the $F2$ layer increased from 4.1 MHz at 19:00 UT to 5.5 MHz at 19:30 UT. A sporadic E_s layer is also identified in the ionograms, but its maximum frequency did not exceed 3.5 MHz. Therefore, in the experiment the HF pump wave ($f_H=4040$ kHz) was certainly reflected from the $F2$ layer.

IMAGE magnetograms for the event on 2 October 1998 are presented in Fig. 2. It can be seen that a substorm activation occurred at 19:30 UT between the SOR (70.54° N) and PEL (66.9° N) magnetic stations. A westward electrojet appeared between the MAS (69.46° N) and MUO (68.02° N)

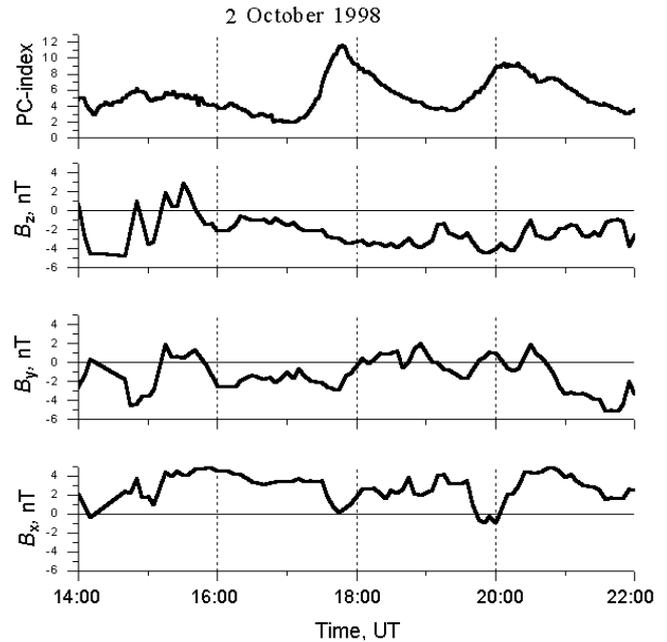

Fig. 1. The temporal behavior of the PC index of the magnetic activity, B_z , B_y , and B_x components of the interplanetary magnetic field on 2 October 1998.

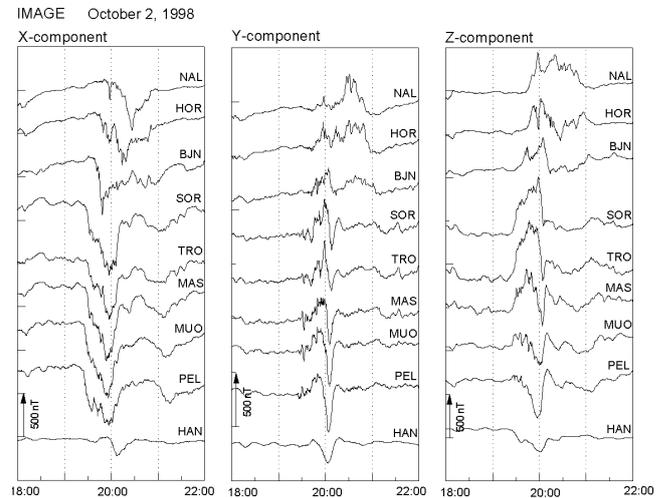

Fig. 2. The temporal behavior of the X , Y , and Z components of the magnetic field variations on 2 October 1998. Data from the IMAGE magnetometers.

stations (reversal of Z component from positive values at MAS to negative values at MUO station and maximum negative values of the X component). This can be clearly seen more accurately from the $X-Z$ profiles obtained from the IMAGE magnetometers (see Fig. 3). Taking into account the tilt of the Tromsø heater antenna beam by 12° to the south and the size of the heated patch in the $F2$ layer, it is possible to conclude that the electrojet appeared in the southern part of the heated patch. The spatial position of the heated patch determined by the diagram of the heater antenna (3 dB contour)

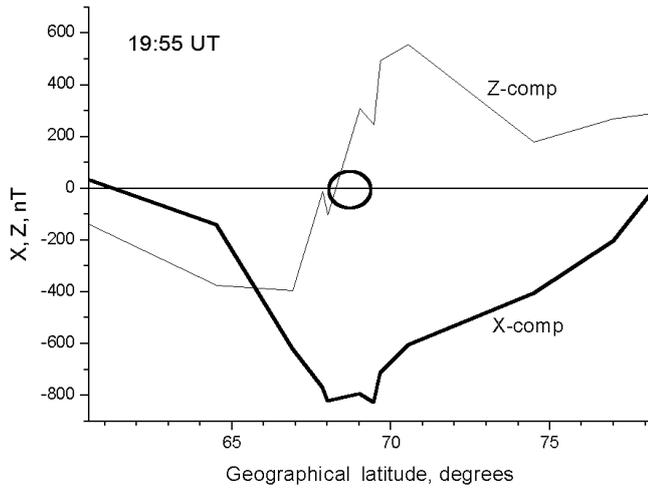

Fig. 3. X – Z latitudinal profiles obtained from IMAGE magnetometers on 2 October 1998, at 19:55 UT. The spatial position of the heated patch at the altitude of 300 km is depicted by a circle.

is also shown in Fig. 3. In reality, from the CUTLASS HF radar measurements the spatial size of the heated patch can occupy a region significantly larger than the area contained within 3 dB contour (Robinson et al., 1998). It is interesting to note that a southward displacement preference was observed in other heater-induced phenomena during other HF pumping experiments, such as the radio-induced airglow (Kosch et al., 2000), and Langmuir turbulence (Isham et al., 1999) which may excite energetic electrons. The behavior of the AE index describing the auroral activity as a whole also shows that the substorm occurred at 19:30 UT.

Figure 4 displays dynamic Doppler spectra of HF diagnostic signals obtained on 2 October 1998, on the London–Tromsø–St. Petersburg path, for a radio scatter operational frequency of 12 095 kHz from 18:57 to 19:46 (Fig. 4a) and from 20:01 to 20:45 UT (Fig. 4b). One can see that during heater-on periods, 19:00–19:08 and 19:15–19:23 UT, the amplification of natural field-aligned irregularities can be recognized in the positive part of the Doppler sonogram. The heater turn-off at 19:23 UT is accompanied by the appearance of continuous noise-like spectral broadening. Then the burst-like noise enhancement in the dynamic Doppler spectra over a frequency range up to 20 Hz starts at about 19:27 UT (see Fig. 4a), i.e. 4 min after the Tromsø heater was turned off at 19:23 UT. It should be noted that the eigenperiod for the Tromsø magnetic flux tube is about 4 min (the Alfvén wave travel time to the magnetic conjugate ionosphere in the Southern Hemisphere and back, along magnetic field line). One might expect that an HF heater turn-off launches an Alfvén wave and leads to the reverberative echo effect in the HF scattered signals, which should manifest itself about 4 min later. This effect was discovered by Yampolski (1989) in SURA heating experiments.

What is the nature of the continuous and burst-like noise enhancements observed from HF Doppler measurements? We have analyzed the magnetic pulsation data recorded near

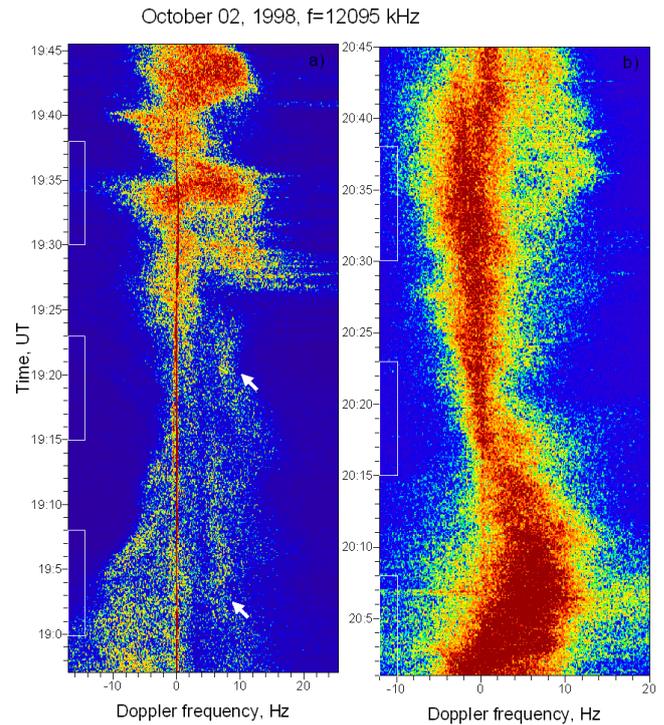

Fig. 4. Dynamic Doppler spectra of HF diagnostic signals on the London–Tromsø–St. Petersburg path on 2 October 1998, at the frequency 12,095 kHz: (a) 18:57–19:46 UT; (b) 20:01–20:45 UT. The direct signals propagating from the transmitter to the receiver along a great circle path correspond to zero Doppler shifts. The intervals when the Tromsø HF heating facility was turned on are marked by bars on the time axis. Arrows on the Doppler sonogram correspond to the signals scattered from the heater-enhanced natural field-aligned irregularities.

Tromsø at Kilpisjärvi (geographical coordinates 69.02° N, 20.79° E). By way of illustration Fig. 5 shows the temporal behavior of H , D , and Z components of the magnetic field variations with 0.1-s temporal resolution and their sonogram (dynamic frequency spectra) in the frequency band of 5 Hz on 2 October 1998, from 19:00 to 19:40 UT. One can see the appearance of continuous pulsations in the frequency range up to 0.8 Hz from 19:23 UT (HF heater turn-off), which can be associated with the Pi1 short-period irregular magnetic pulsations of the PiC type. Thereafter, against this background the well-defined burst-like signals at frequencies up to 2.4 Hz are recognized from the sonogram. In accordance with classification of magnetic pulsations, these signals are identified as PiB magnetic pulsations. It should be pointed out that PiC and PiB magnetic pulsations are observed in all components (H , D , Z) of the magnetic field. The comparison between HF Doppler scatter and magnetic pulsation data shows clearly the following. Features in the dynamic Doppler spectra of HF diagnostic signals, such as continuous and burst-like noise enhancements, may be attributed to PiC and PiB magnetic pulsations, correspondingly. In this respect it is significant that PiB pulsations correspond to the trapping of Alfvén wave energy in the ionospheric Alfvén

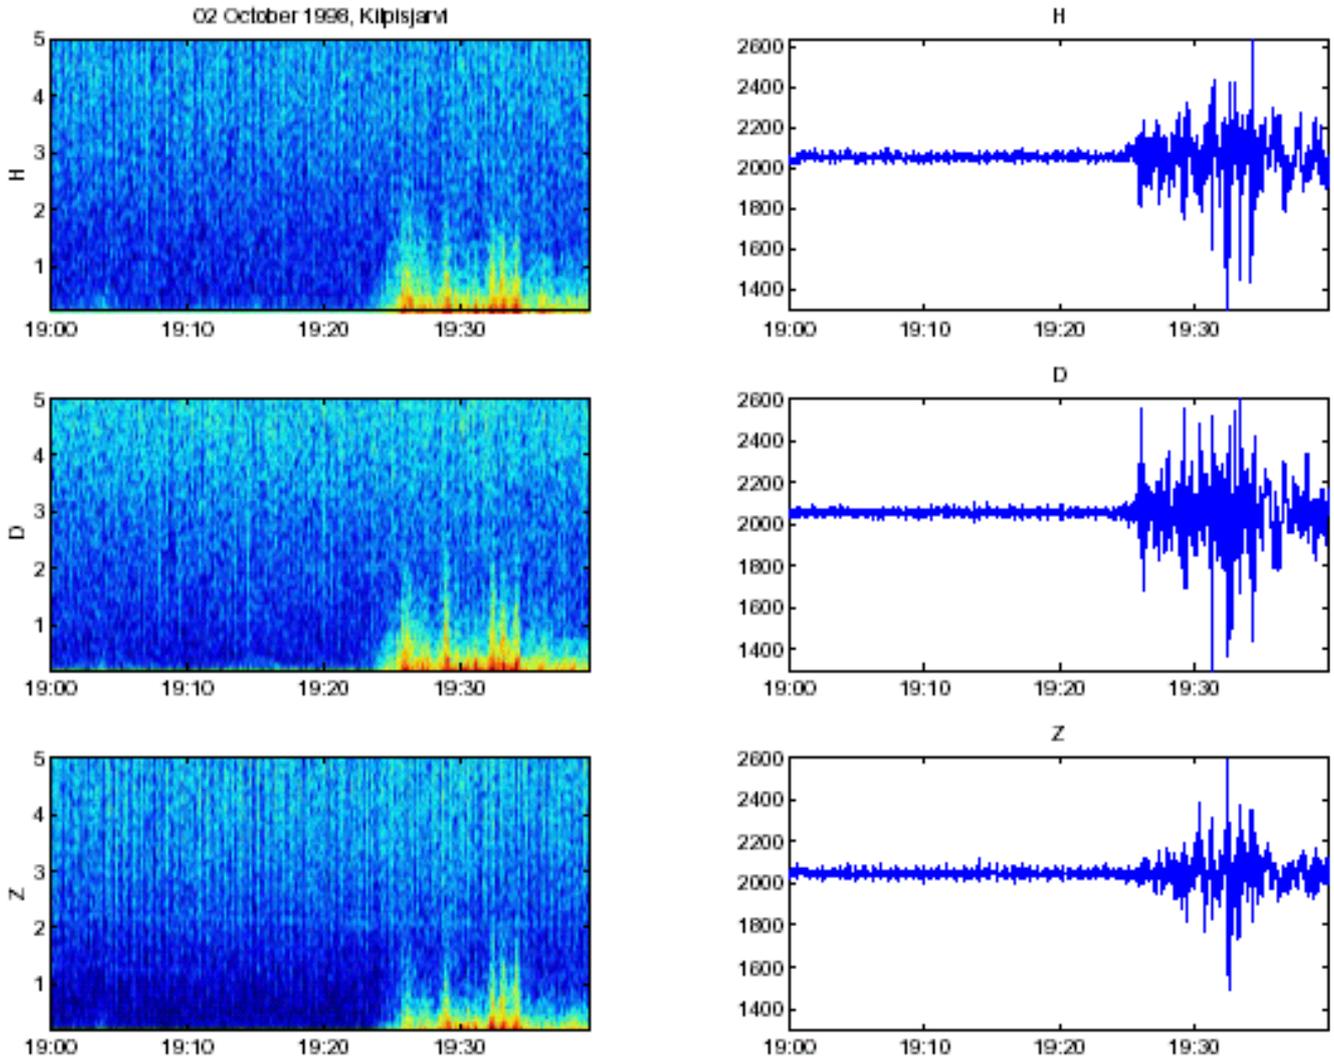

Fig. 5. H , D , and Z components of magnetic pulsations recorded at Kilpisjarvi on 2 October 1998, and their sonograms (dynamic frequency spectra) in the frequency range from 0.2 to 5 Hz.

resonator, IAR (Lysak and Song, 1998) or, in other words, to the generation of Alfvén vortices (short-scale oblique Alfvén waves) captured in the IAR (Trakhtengerts and Feldstein, 1991; Trakhtengerts et al., 2000). Recall that the IAR eigenfrequencies lie within the range 0.1–10 Hz; they manifest themselves in the spectra of magnetic pulsations, as well as in the electromagnetic noise (Belyaev et al., 1999; Trakhtengerts et al., 2000). Therefore, there are reasons to assume that the observed electromagnetic noise, and PiC and PiB magnetic pulsations can be the manifestation of an excitation of the Alfvén vortices trapped in the ionospheric Alfvén resonator.

The other distinctive feature in the dynamic Doppler spectra of the scattered HF signals is the generation of an intense wave process with periods of 7–8 min. It started at 19:30 UT after the heater was turned on. The observed ionospheric wave disturbance is likely to be the signature of short-period atmospheric gravity waves, AGWs (Hunsucker, 1982). It is

conceivable that an AGW can be launched by strong heater-enhanced electric fields via Joule heating and an indication of this has been observed in Arecibo (Thidé et al., 1989). Thereafter, the ionospheric wave process which takes place is not dependent on whether the Tromsø heater is turned on or off. At substorm maximum (about 20:00 UT) a large-scale ionospheric wave disturbance was generated above Tromsø. It was observed throughout the recovery phase of the substorm. Its period was more than 45 min (see Fig. 4b). Similar wave disturbances are usually considered typical signatures of intense magnetospheric substorms and storms.

Interesting features in the ionospheric plasma parameters were observed by the EISCAT UHF incoherent scatter radar at Tromsø, pointing in the magnetic field-aligned direction (77°). Figure 6 presents temporal variations of the electron density N_e , ion and electron temperatures (T_i and T_e), the ratio of T_e/T_i , and ion velocities V_i obtained on 2 October 1998, from 18:57 to 20:10 UT at altitudes of 300, 430, and

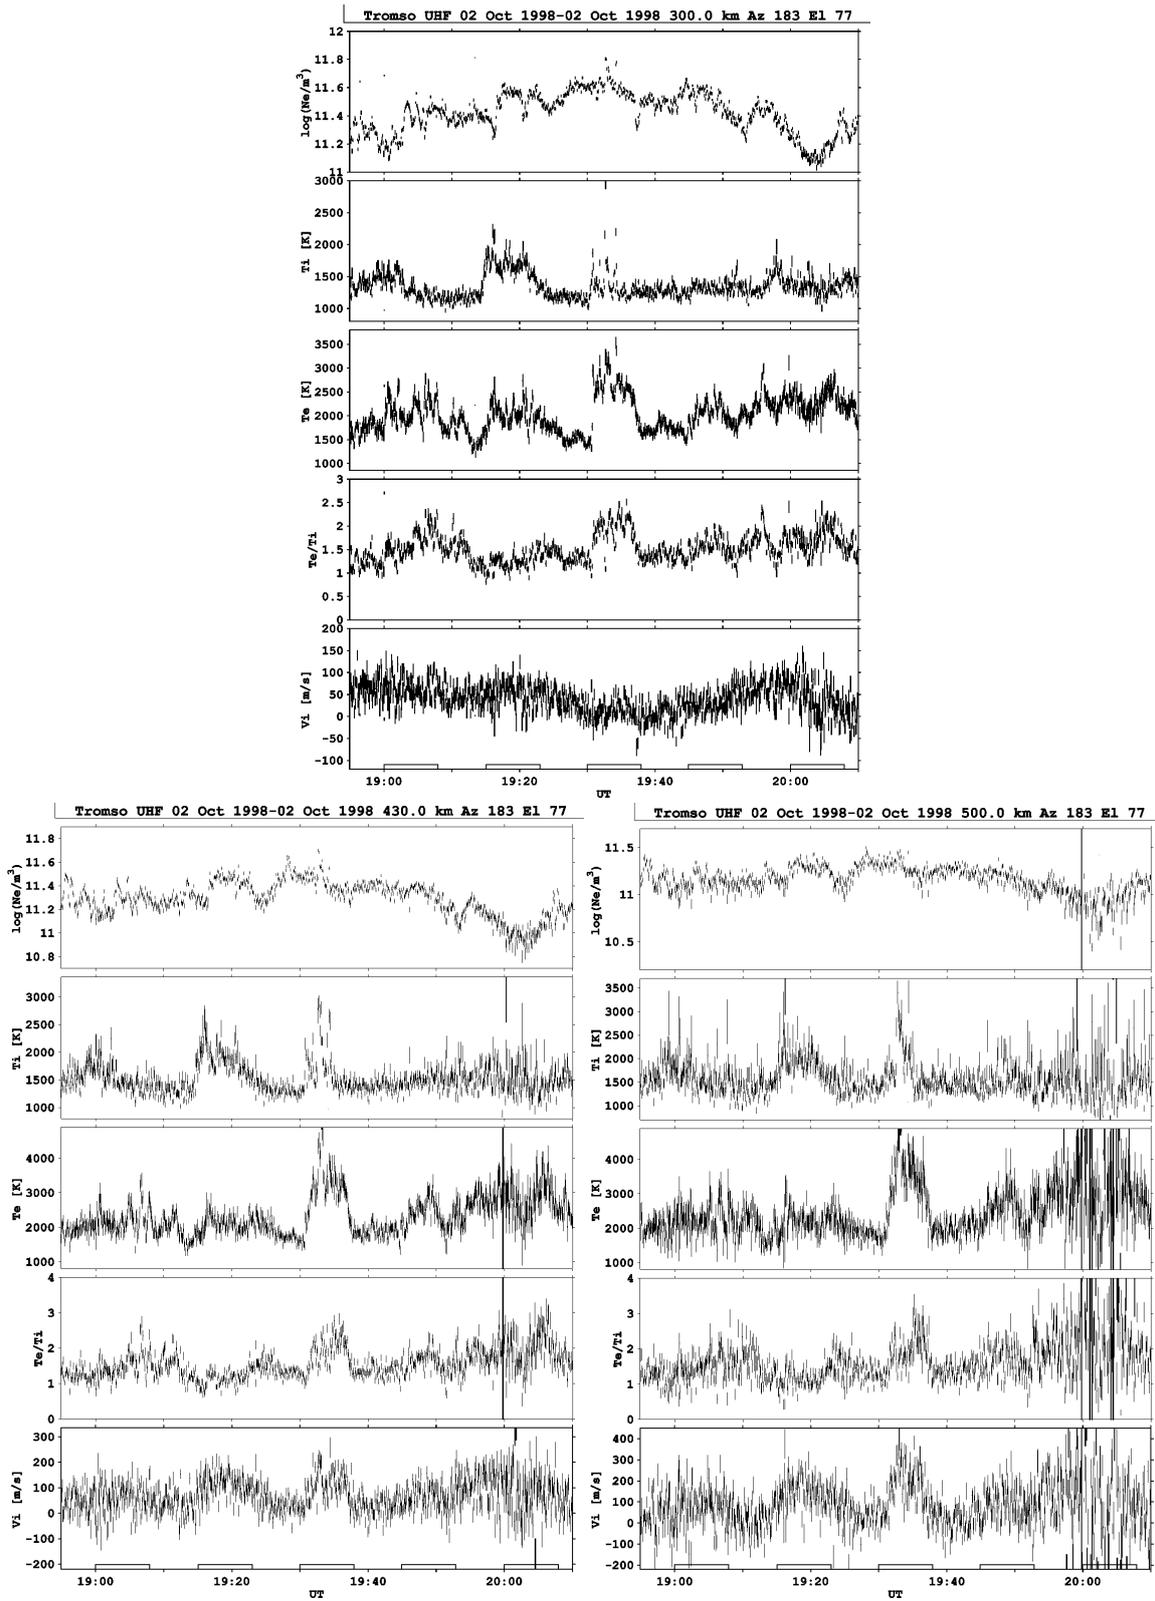

Fig. 6. The temporal behavior of the electron density N_e , ion temperature T_i , electron temperature T_e , the ratio of the T_e/T_i , and ion velocities V_i as observed with the Tromsø EISCAT UHF incoherent scatter radar in the field-aligned direction on 2 October 1998, from 18:56 to 20:10 UT at altitudes of 300, 430, and 500 km. EISCAT UHF radar data are obtained by using the long-pulse and analyzed with 20-s integration time. The intervals when the Tromsø HF heating facility was operated are marked by bars on the time axis. The Tromsø HF heating facility was operated with a 8-min on, 7-min off pump cycle (4-min 50% full power, 4-min 100% power then 7-min off).

Table 2. The mean values, the standard deviations, the standard errors of the means, the minimum and maximum values of the T_e and T_i at altitudes of 315 and 517 km calculated during the heater-on and heater-off periods on 2 October 1998.

500 km. Note that the EISCAT UHF radar was probing in the geomagnetic field-aligned direction. From Fig. 6 one can see very strong T_e enhancements, closely related to the consecutive heater-on periods from 19:00–19:08, 19:15–19:23, 19:30–19:38, and 19:45–19:53 UT. Enhancements in T_e were observed over a wide altitude range from 200 to 600 km (the upper altitude limit of the EISCAT UHF radar measurements in the experiment). It is common knowledge that HF pump-induced electron heating, as well as the excitation of artificial field-aligned irregularities (AFAI) and the anomalous absorption, is a phenomenon related to the upper hybrid wave. It is generated at the vicinity of the upper hybrid resonance (UHR) altitude, where the heater frequency f_H is equal to the local upper hybrid frequency, $f_H^2 = f_0^2 + f_{ce}^2$ (f_0 is the local plasma frequency and f_{ce} is the electron gyrofrequency). The UHR height is several kilometers below from the reflection level of the HF pump wave. In the course of the experiment on 2 October 1998 very strong electron temperature enhancements were observed in a wide altitude range well above the reflection level of the HF waves. Enhancements in T_e were accompanied by strong T_i increases along with positive (upward) ion velocities from altitudes above 350 km.

The variations in T_e and T_i during the heater on and off cycles are stronger under disturbed magnetic conditions than under quiet conditions. There is a good reason to compare the mean values of T_e and T_i during heater-on and heater-off periods. For this purpose 10-s resolution data from the EISCAT UHF radar measurements at altitudes of 315 km

(near the reflection level of the HF pump wave) and 517 km, that is well above the reflection altitude of the powerful HF radio wave, were employed. Calculation results of the means, the standard deviations, and the standard errors of the means are summarized in Table 2, where one can see that the means and standard deviations of the T_e and T_i in all heater-on cycles exceed the same parameters calculated in heater-off periods at both altitudes of 315 and 517 km.

The positive V_i , indicative of the generation of upward ion flows, reached their maximum values (about 400 m/s at the height of 500 km) in the heater-on period from 19:30–19:38 UT, corresponding in time to the substorm onset. Note that the HF pump waves modify significantly the ionospheric plasma, even after the substorm onset. During the heater-on period, from 19:45 to 19:53 UT there are the T_e enhancements, as well as a generation of heater-induced upward ion flow.

Large electron temperature enhancements (a doubling) produced by strong HF pump waves during winter night hours were observed at Arecibo (Djuth et al., 1987). These T_e enhancements were measured in a narrow altitude range near the upper hybrid resonance (UHR) height. Recent experimental results from Tromsø HF pumping experiments in the nightside ionospheric F -region during quiet magnetic conditions (Rietveld et al., 2003) clearly demonstrate not only extremely strong T_e enhancements in a wide altitude range, but also increases in the ion temperatures of about one hundred degrees and the generation of upward ion flows

Table 3. Background geophysical conditions in the course of the HF pumping experiments.

along magnetic field-aligned direction as well. Moreover, the strongest pumping effects occurred when the powerful HF radio wave is beamed along magnetic field line.

Even though the HF pumping effects observed in the experiment on 2 October 1998 resemble the effects observed by Rietveld et al. (2003), there is a clear distinction between them. On 2 October 1998 strong T_e increases with altitude are measured, especially at the beginning of a heater-on period corresponding to the substorm onset, when $T_e=2800$ K at the altitude of $h=300$; they reach the values of $T_e=5000$ K at $h=500$ km.

The T_i enhancements most pronounced in the heater-on periods from 19:15–19:23 and 19:30–19:38 UT may be attributed to the increase in the ionospheric electric field. In this respect it should be mentioned that a very strong T_i increase, accompanied by drastic enhancements in the ionospheric electric field, was observed during the triggering of the local auroral activations when HF pumping was made into the nightside auroral E region (Blagoveshchenskaya et al., 2001). A substantial doubling of the southward-pointing convection electric field caused by HF heating was also measured from a sounding rocket inside of the Arecibo HF heater beam (Peria and Kelley, 2001).

The origin of heater-induced upward ion flows in HF ionospheric modification experiments is not clear. Ion upflow events from EISCAT UHF radar measurements, observed naturally in the F region, can be divided into two types as described by Wahlund et al. (1992). Type I events are related to the strong perpendicular electric field E_0 , enhanced T_i due to frictional heating and low electron densities (thermal plasma outflow). Type II upflows are associated with active auroral conditions and increased electron temperatures T_e . They may be related to enhanced parallel electric field E_{\parallel} along magnetic field-aligned direction caused by anomalous resistivity due to ion acoustic turbulence. Forme and Fontaine (1999) have found that ion acoustic turbulence can greatly increase the electron temperature, leading to the upward ion acceleration by enhanced field-parallel electric field. In the course of the experiment on 2 October 1998, carried out during dis-

turbed background conditions, the occurrence of upward ion flows was observed in conjunction with greatly increased both T_e and T_i . Moreover, the appearance of ion upflows was accompanied by heater-enhanced ion lines after turn-on of the Tromsø HF heater, which is indicative of ion acoustic turbulence. Heater-enhanced ion lines were measured at 19:00:05, 19:15:05, and 19:30:05 at altitudes of 303, 267, and 248 km, correspondingly. Heater-enhanced ion lines are observed at altitudes in the close vicinity of the reflection height of the powerful HF radio wave. One may speculate that the generation of the heater-driven upward ion flows may be related to the parallel electric field. Nonetheless, we do not exclude the other ion acceleration mechanisms which can operate in the HF modified auroral ionosphere.

Summarizing the experimental findings from the multi-instrument observations in the course of the Tromsø HF pumping experiment on 2 October 1998, one can distinguish the following features related to the auroral activation: (1) amplification of natural field-aligned irregularities during heater-on periods; (2) possible appearance of the reverberative echo effect in the HF scattered signals that manifests itself about 4 min (eigenfrequency of the Tromsø L -shell) after the HF heater was turned off; (3) burst-like electromagnetic noise enhancements in the dynamic Doppler spectra of HF scattered signals accompanied by PiB magnetic pulsations that can be associated with the trapping of Alfvén wave energy in the ionospheric Alfvén resonator; (4) strong T_e and T_i enhancements in a wide altitude range driven by HF pumping; (5) generation of the heater-induced intense upward ion flows along the magnetic field lines; (6) strong T_e increases with altitude during heater-on period corresponding to the substorm onset; (7) substorm onset in the southern part of the heated patch under a steady southward B_z component of the IMF.

4 Distinctive features related to the auroral activations

In this section we summarize and compare the distinctive features related to auroral activations from Tromsø HF pumping experiments in the nightside auroral ionosphere under the reflection of HF pump wave from $F2$ layer (Sect. 3), as well as from the sporadic E_s layer (Blagoveshchenskaya et al., 2001).

First of all, there is a need to examine the background geophysical conditions during the HF pumping experiments. From Table 3 one can see that the experiments on 16 and 17 February 1996 were conducted under slightly disturbed magnetic conditions. The values of the K_p index were about $K_p=2-3$ and $15 \leq \Sigma K_p \leq 18$. During the experiment on 2 October 1998, the magnetic conditions were disturbed, and values of the K_p index were $K_p=5$ and $\Sigma K_p=33$.

The distinctive features related to four auroral activations from multi-instrument observations are summarized in Table 4. Let us consider these characteristics in more detail. The generation of wide band spectral features in the Doppler radio scattering data was observed in all

Distinctive features from different observational methods	Auroral activations onsets, date and time, UT

experiments. As it was shown in Sect. 3, there is the association of electromagnetic noise enhancements from HF Doppler observations with Pi1 magnetic pulsations. It can be indicative of ionospheric Alfvén resonator effects (Trakhtengerts et al., 2000). What are the possible mechanisms needed for the excitation of ionospheric Alfvén resonator effects due to unmodulated HF heating of the Earth’s ionosphere? Clearly, to answer this, new theoretical approaches and special-oriented experiments are needed.

The strong increases of the ion temperatures, as well as the local ionospheric electric fields, observed in all events analyzed can be explained in terms of the theory for non-resonant local variations of the macroscopic electric field developed by Trakhtengerts et al. (2000). Peria and Kelley (2001) have proposed the ponderomotive force and temperature gradients, both of which are ubiquitous during HF heating, as the candidate mechanisms for the heater-induced ionospheric electric field.

Modification of the auroral arc and local spiral-like formation is seen in all experiments under reflection of the HF pump wave from the sporadic E_s layer, see Plates 1 and 2 of Blagoveshchenskaya et al. (2001). Unfortunately, the optical observations were not carried out when the powerful HF radio wave was reflected from $F2$ layer (experiment on 2 October 1998).

Nevertheless, there are some effects observed only on 2 October 1998, when the $F2$ layer was overdense, during disturbed magnetic conditions (see Tables 3 and 4). Only the latter experiment show evidence for a generation of intense heater-induced upward ion flows (ion velocities up to 400 m/s at the altitude of 500 km), strong enhancement of the electron temperature T_e along the magnetic field-aligned direction in a wide altitude range from 200 to 600 km (upper limit of the EISCAT UHF radar measurements during the experiment), and strong T_e increases with altitude during the heater-on

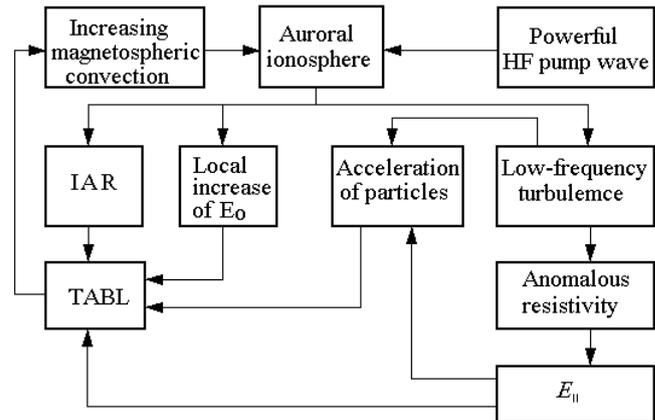

Fig. 7. A possible scheme for the triggering of local auroral activations due to HF pumping into nightside auroral ionosphere. IAR is the ionospheric Alfvén resonator; TABL is the turbulent Alfvén boundary layer.

period, corresponding to the substorm onset. Furthermore, in the latter experiment, auroral activation occurred in a localized latitudinal region that extends to larger scales with a latitudinal width of 3° (see Sect. 3) as compared to the activations on 16 and 17 February 1996 (latitudinal width of 1°) observed by Blagoveshchenskaya et al. (2001).

Strong electron temperature enhancements and a southward shift of the strongly heated region can apparently be explained by the theory of self-focusing on striations of the HF pump wave developed by Gurevich et al. (2001). This theory describes a formation of a large-scale nonlinear structure along the magnetic field line, consisting of a number of bunches of striations (solitons). It is interesting to mention that in experiments at Arecibo, direct measurements of striations were performed by Kelly et al. (1995). The nonlinear structuring is also manifested in observations (Kelly et al., 1995; Franz et al., 1999). It should be pointed out that the generation of striations and the large-scale nonlinear structuring at Arecibo is much more difficult than at high latitudes (Gurevich et al., 1999).

It was shown by Bernhardt et al. (1988) that HF pump-induced ohmic and anomalous heating increases the electron temperature and the plasma pressure in the heated patch, which, in turn, accelerates the plasma along the magnetic field lines. Upward ion flows were predicted by Vas’kov et al. (1993) for the Arecibo case based on a model with a solitary ion-acoustic compression wave propagating along the field-aligned direction. Mingaleva and Mingalev (1997) performed modelling for conditions of the high-latitude ionosphere.

In spite of numerous radar and satellite observations of ion upflows at auroral latitudes, see, for example, Foster et al. (1998), the initial mechanisms that preheats the ionospheric ions, which then propagate upward along magnetic field lines due to the parallel electric field and mirror force, are widely debated. Postulated mechanisms include

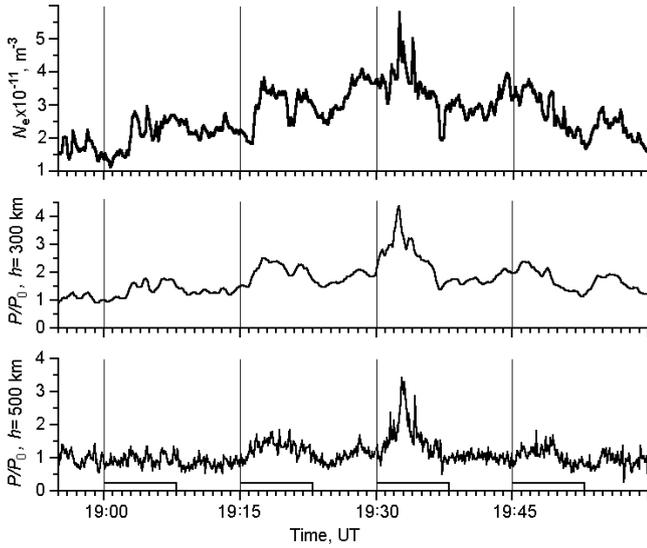

Fig. 8. The temporal behavior of the electron density N_e at the altitude of 300 km from the EISCAT UHF radar measurements, relative values of partial pressure P/P_0 at the altitudes of 300 and 500 km in the course of the Tromsø HF pumping experiments on 2 October 1998, from 18:55 to 20:00 UT. The intervals when the Tromsø heater was turned on are marked by bars on the time axis.

ion frictional heating due to the perpendicular electric field (Baron and Wand, 1983), lower hybrid waves, ion cyclotron waves, and solitons (Forme and Fontaine, 1999; Ogawa et al., 2000; Kovtyukh, 2001; Mälkki and Lundin, 1994), stochastic ion heating on short perpendicular wavelength electrostatic waves and structures (Stasiewicz et al., 2000). Note that multiple acceleration processes may be operative along magnetic field lines at different altitudes (Sagawa et al., 1991).

5 Possible mechanisms for the triggering of auroral activations

A possible scenario for the substorm triggering due to HF pumping into the nightside auroral ionosphere along magnetic field-aligned direction is illustrated by the scheme in Fig. 7.

The accumulation of the energy in the magnetospheric tail due to the solar wind-magnetosphere interaction is accompanied by an increase in the laminar magnetospheric convection. Thermal nonlinear interaction between powerful HF radio waves and the auroral ionospheric plasma leads to a local increase in the ionospheric electric field E_0 (Blagoveshchenskaya et al., 2001), the excitation of the ionospheric Alfvén resonator (IAR) and low-frequency turbulence. The enhanced currents lead to Alfvén wave trapping in the ionospheric Alfvén resonator, which is bounded from below by the heater-modified E region and from above by the region of a sharp increase in the Alfvén velocities at altitudes up to one Earth radius (Trakhtengerts and Feldstein, 1991). Models predicting changes in the ionospheric conductivity and

feedback instability in the magnetosphere-ionosphere system were developed by Lysak (1990, 1991), Trakhtengerts and Feldstein (1991), and Stasiewicz et al. (2000).

Heater-induced low-frequency turbulence leads to a field-aligned potential drop in the magnetic flux tube, anomalous resistivity, and the development of a parallel electric field E_{\parallel} . It was found by Haerendel (1990) that the parallel electric field may be responsible for the decoupling of the magnetospheric convection from the ionosphere. The enhanced ionospheric electric field, the parallel electric field, the turbulent plasma heating, and the acceleration of runaway charged particles are possible mechanisms for the Alfvén wave dissipation in the ionospheric Alfvén resonator which, in turn, leads to the excitation of the turbulent Alfvén boundary layer (TABL) or, in other words, Alfvén vortex instability (AVI) in the IAR (Trakhtengerts and Feldstein, 1991; Trakhtengerts et al., 2000). It may serve as a trigger of the auroral activation.

It is of interest to estimate possible changes in the ionospheric electric field E_0 and the parallel electric field E_{\parallel} during HF pumping experiments at high latitudes. It has been predicted by Trakhtengerts et al. (2000) that a strong local increase of E_0 can occur near the “nose” of the heater-modified ionospheric region, if the disturbed region is elongated along the background electric field E_0 and the disturbance is large. In this case the amplitude of the electric field E_m near the nose of the heater-modified ionospheric region is of the order of $E_m \approx 3.5 E_0$ (Trakhtengerts et al., 2000), which is close to that which we observed from the EISCAT UHF radar measurements in HF heating experiments (Blagoveshchenskaya et al., 2001).

Assuming charge neutrality, J_z can be estimated by (Kamide and Baumjohann, 1993)

$$J_z = \Delta n e V_{\parallel}, \quad (2)$$

where Δn is the change in the electron density, V_{\parallel} is the field-aligned current velocity, e is the electron charge.

Figure 8 displays the temporal behavior of the electron density N_e at an altitude of 300 km, as measured by the EISCAT UHF radar during the HF pumping experiment on 2 October 1998, as well as the calculated values of the relative plasma partial pressure P/P_0 at altitudes of 300 and 500 km. The condition of the hydrodynamical equilibrium is fulfilled when the partial pressure is kept constant, $P = N_e(T_e + T_i) = \text{const}$.

Therefore, the values of P/P_0 can be written as (Gurevich, 1978)

$$P/P_0 = \frac{N_e(T_e + T_i)}{N_{e0}(T_{e0} + T_{i0})}, \quad (3)$$

where T_{e0} , T_{i0} , and N_{e0} are the electron and ion temperatures, and the electron density before the HF heater is turned on; T_e , T_i , and N_e are the same parameters in the course of the heater-on periods. From Fig. 8 one can see that the hydrodynamical equilibrium has been disrupted due to the effects of powerful HF radio waves. The strongest increase in the

partial pressure takes place in the heating cycles at 19:15–19:23 and 19:30–19:38 UT. Furthermore, heater-induced effects in the behavior of P/P_0 were observed at the altitudes of 300 and 500 km as well.

We speculate that there are two electron populations during heater-on periods. One of them is the downward field-aligned current carrying heater-induced runaway electrons from the ionosphere. The other one is the electron precipitation from the magnetosphere carrying the background upward field-aligned current, responsible for the formation of the substorm current system (Boström, 1964; Kan, 1993; Haerendel, 1990; Kamide and Baumjohann, 1993; Rostoker, 1999). The presence of two electron populations in HF pumping experiments is confirmed by direct observations from the FAST satellite (Robinson et al., 2000). One might expect that the heater-induced runaway electron population may promote the development of current-driven instabilities which, in turn, leads to the decoupling of magnetospheric convection from the ionosphere. This corresponds to the onset of auroral activation.

The field-aligned current velocity V_{\parallel} can be obtained from the condition of a current convective instability growth (Ossakow and Chaturvedi, 1979)

$$\frac{V_{\parallel}}{L_N} \geq \frac{(T_e + T_i)k_{\parallel}^2}{m\nu_e} \sqrt{\frac{M}{m} \frac{\nu_{in}}{\nu_{en}}}, \quad (4)$$

where m and M , T_e and T_i are the electron and ion masses and the temperatures, respectively; ν_{en} and ν_{in} are collision frequencies of electrons/ions with neutrals; $\nu_e = \nu_{en} + \nu_{ei}$, where ν_{ei} is the Coulomb collision frequency; L_N is a typical scale of the perpendicular plasma density gradient; k_{\parallel} is the field-aligned wave number of irregularities. For V_{\parallel} calculations, the T_e and T_i values were taken from the EISCAT UHF radar measurements. We assume that $L_N = 1$. The collision frequencies ν_{en} , ν_{ei} , and ν_e were calculated by taking into account the values of T_e , N_e , N_n , and N_i . Calculations of the neutral component N_n on 2 October 1998 versus altitude and time were made by using MSIS-E-90 Model (<http://nssdc.gsfc.nasa.gov/space/model/models/msis.html>). The field-aligned wave number of irregularities k_{\parallel} is found, taking into account the ratio of field-aligned to cross-field scales $l_{\parallel}/l_{\perp} \sim 2 \cdot 10^3$ (Kagan and Frolov, 1996). In the course of our experiments, the bistatic HF Doppler radio scatter used the 12 095 and 9410 kHz carrier signals from London transmitters and therefore was sensitive to irregularities with spatial scales $l_{\perp} \approx 12$ –15 m.

From expression (4) and with the use of the experimental values of $T_e = 2500$ –3000 K and $T_i = 1700$ –2500 K at the altitude of 300 km and $T_e = 3200$ –5000 K and $T_i = 2000$ –3500 K at the altitude of 500 km, the field-aligned current velocity V_{\parallel} is estimated to be in the range $2 < V_{\parallel} < 4 \text{ km} \cdot \text{s}^{-1}$ at $h = 300$ km and in the range $5 < V_{\parallel} < 15 \text{ km} \cdot \text{s}^{-1}$ at $h = 500$ km.

Rough estimates of the parallel electric field E_{\parallel} can be made from the expression (Ginzburg, 1967)

$$E_{\parallel} \sim \frac{m}{e} V_{\parallel} \sqrt{\omega^2 + \nu_e^2} \sqrt{\frac{2m}{M}}, \quad (5)$$

where V_{\parallel} is the field-aligned current velocity from Eq. (4), ω is the plasma frequency, and m , M , e , and ν_e are the same as in Eq. (4).

Setting $V_{\parallel} = 2$ –4 $\text{km} \cdot \text{s}^{-1}$ at $h = 300$ km and $V_{\parallel} = 5$ –15 $\text{km} \cdot \text{s}^{-1}$ at $h = 500$ km for a pump frequency of 4040 kHz, we find that $E_{\parallel} = (10$ –15) $\text{mV} \cdot \text{m}^{-1}$ at the altitude 300 km and $E_{\parallel} = (20$ –40) $\text{mV} \cdot \text{m}^{-1}$ at the altitude 500 km.

Summarizing the results of the calculations, one can distinguish the following: (1) the hydrodynamical equilibrium has been disrupted due to the effects of HF pumping into the nightside auroral ionosphere; (2) the partial pressure of ionospheric plasma is about four times higher during the substorm onset than the background level just before the HF heater was turned on; (3) the parallel electric field can reach the values of the order of $E_{\parallel} = 30 \text{ mV} \cdot \text{m}^{-1}$ during the substorm onset at 19:30 UT.

6 Summary

We suggest that the results obtained provide evidence that HF pumping into nightside auroral ionosphere along the magnetic field-aligned direction produces a modification of the magnetosphere-ionosphere coupling. It is expected that a local heater-driven current system is formed which, in turn, under certain geophysical conditions may cause triggering of auroral activations.

Distinctive features related to auroral activations in the course of the Tromsø HF pumping experiments are identified. Typical peculiarities observed in all events are the following: (1) the generation of burst-like electromagnetic noise observed in bistatic HF Doppler scatter measurements; (2) a strong increase in the ion temperature T_i and the local ionospheric electric field E_0 ; (3) modification of the auroral arc and local spiral-like formation. However, some features were observed only when the HF pump wave was reflected from the F_2 layer under disturbed magnetic conditions. Only the latter experiment shows evidence of strong T_e increases with altitude, especially during the triggering of auroral activation. The generation of the intense upward ion flows, strong enhancement of the electron temperature T_e in a wide altitude range (from 200 km to the upper altitude limit of the EISCAT UHF incoherent scatter radar which was 600 km during experiment) are also observed in this experiment.

A possible scenario for the substorm triggering due to the excitation of the turbulent Alfvén boundary layer (TABL), or in other words, Alfvén vortex instability (AVI), by an unmodulated HF pump wave in the ionospheric Alfvén resonator (IAR) is considered. In this respect the potentiality of the IAR excitation by an unmodulated HF pump wave is discussed. The comparison between electromagnetic noise enhancement from HF Doppler scatter measurements and PiC and PiB types of Pi1 magnetic pulsations points to an association between them. Taking into account that Alfvén wave energy can be trapped in the IAR causing PiB magnetic pulsations, the appearance of the burst-like noise

enhancement on the Doppler sonogram and PiB magnetic pulsations can be indicative of ionospheric Alfvén resonator effects. Clearly, further experiments and new theoretical approaches are needed.

The enhanced ionospheric electric field, parallel electric field, and turbulent plasma heating are possible mechanisms for Alfvén wave dissipation in the IAR that leads to the excitation of the TABL. One would expect that the heater-induced runaway electrons may promote the development of current driven instabilities and the formation of an additional acceleration region at low altitudes (350–1000 km). The hydrodynamical equilibrium has been disrupted due to effects of HF pumping. The partial pressure is about four times greater during the substorm onset than the background level.
