DOI: 10.1039/b000000x

The organic/inorganic hybrid perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$ is a novel light harvester, which can greatly improve the solar-conversion efficiency of dye-sensitized solar cells. In this study, a first principle theoretical study is performed using local, semi-local and non-local exchange-correlation approximations to find a suitable method for this material. Our results, using the non-local optB86b+vdWDF functional, excellently agree with the experimental data. Thus, consideration of weak van der Waals interactions is demonstrated to be important for the accurate description of the properties of this type of organic/inorganic hybrid materials. Further analysis of the electronic properties reveals that I 5p electrons can be photo-excited to Pb 6p empty states. The main interaction between the organic cations and inorganic framework is through the ionic bonding between CH_3 and I ions. Furthermore, I atoms in the Pb-I framework are found to be chemically inequivalent because of their different chemical environments.

1. Introduction

Dye-sensitized solar cells (DSCs) have stood out among various photovoltaic devices owing to their low cost, simple fabricating procedure, environment friendliness, and relatively high efficiency. Consequently, DSCs are promising candidates for the next generation of solar cells.¹⁻³ One recent breakthrough on DSCs is the introduction of organic/inorganic hybrid perovskite materials as novel light harvesters, such as $\text{CH}_3\text{NH}_3\text{PbI}_3$, which can improve the solar conversion efficiency of DSCs to the current best record, ca. 15%.⁴⁻¹⁰ The high efficiency has been demonstrated to the long exciton diffusion lengths in the perovskite materials.¹¹⁻¹² Therefore, understanding the structures and chemistries of these prototype light harvesters is important for the molecular design of organic/inorganic perovskite materials with defined properties.

Perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$ was synthesized and characterized

by Weber at 1978.¹³ He found that each Pb^{2+} cation is coordinated to six I anions to form $[\text{PbI}_6]$ octahedra, which are corner-connected to each other form a three-dimensional Pb-I framework. Each CH_3NH_3^+ cation locates at the centre of four $[\text{PbI}_6]$ octahedra. Thus, each cation interacts with 12 I anions.¹⁴⁻¹⁵ Previous experiments demonstrate that the symmetry and structure of $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystals are highly dependent on the temperature.¹⁵ At low temperature, an orthorhombic phase (space group: *Pnma*) is found. The orthorhombic phase transforms into a tetragonal structure (space group: *I4/m*) above 161.4 K. The cubic phase (space group: *Pm-3m*) is observed when the temperature is higher than 330.4 K. The improved symmetry at the higher temperature is experimentally proposed to be related to the fast dynamic movement of CH_3NH_3^+ cations within the Pb-I framework. As a result, the location of CH_3NH_3^+ cations can only be determined experimentally in the orthorhombic phase at low temperature.¹⁵ At the same time, the lattice constants of the orthorhombic crystal vary little at the low temperature.¹⁵ Therefore, this investigation is focused on the orthorhombic perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$.

Both structural and electronic properties of organic/inorganic hybrid perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystals are investigated in the present *ab initio* calculations. Density functional theory (DFT) is employed as it offers an efficient, yet accurate quantum mechanical method for theorists to optimize structures, determine energies of reactants and products, examine the nature of intermediates, and predict the reaction energies for elementary steps.¹⁶⁻¹⁹ However, there are still areas where traditional DFT

with local density (LDA) or generalized gradient (GGA) approximations has its difficulties, such as the depiction of the van der Waals (vdW) interactions.²⁰ This is because the local (LDA) or semi-local (GGA) exchange-correlation (XC) functional approximations neglect the necessary ingredients to describe non-local vdW interactions. The vdW force plays an important role in a range of systems with weak interactions, such as organic/inorganic hybrid materials, particularly in their geometries.²¹ Recently, GGA/DFT calculations have been performed to analyse the electronic properties of cubic, tetrahedral and orthorhombic CH₃NH₃PbI₃. In their study, the experimental structures were employed without consideration of vdW interactions.¹⁵ Thus, to get a precise theoretical understanding of organic/inorganic hybrids, methods beyond traditional DFT are required.

In the last decade, empirical and less empirical approaches have been developed for prediction of vdW interactions in the DFT context.²²⁻²³ The vdW-DF class of dispersion energy functionals is generally considered to be a good choice for large systems, except possibly for weakly bound layers,²³⁻²⁴ or where strongly non-additive effects are important.²⁵⁻²⁷ For the present system, a remaining issue regarding vdW-DF comes from the choice of associated semi-local exchange functionals. Here we will use a recently-proposed semi-local functional optB86b that has been shown to work well in conjunction with vdW-DF for the cohesive properties of conventional solids.²⁸ To confirm the importance of vdW effects for the properties of CH₃NH₃PbI₃, a systematic study using local, semi-local, and non-local XC functionals is performed herein. We present results for fully optimized structures, density of states, band structures, and charge distributions, which are compared with the available experimental data.

2. Computation Details

All the theoretical computations are performed by using the Vienna *ab initio* simulation package (VASP) based on DFT with the all-electron projected augmented wave (PAW) method in this study.²⁹⁻³⁰ Electron-ion interactions are described using ultrasoft pseudopotentials with a kinetic energy cut-off of 520.0 eV.³¹ Valence states included the Pb 6s, 6p, and 5d states, I 5s and 5p

states, C 2s and 2p states, N 2s and 2p states, and the H 1s states. When the geometry is optimized, all atoms are allowed to relax. The cell optimization technique is employed to optimize the lattice constants. We perform Brillouin-zone integrations using Monkhorst-Pack grids of special points with (4×4×4) and (8×8×8) meshes for the calculations of structural and electronic properties, respectively. The supercell of orthorhombic CH₃NH₃PbI₃ includes 48 atoms.

A range of specific functionals have been developed for local LDA, semi-local GGA, and non-local vdW-DF approaches previously. In this study, typical functionals for each approach have been chosen to represent their respective class. The functionals parameterized by (PZ81)³² and Perdew-Burke-Ernzerhof (PBE)³³ are employed for local LDA and semi-local GGA methods, respectively. Here, we use the non-local vdW-DF method proposed by Dion et al. to describe the vdW interaction as modified by Klimes et al.^{23,28} In this approach, the XC energy E_{XC} takes the form:

$$E_{XC} = E_X^{GGA} + E_C^{LDA} + E_C^{nl}$$

Here the exchange energy E_X^{GGA} uses the optimized optB86b GGA functional,²⁸ and E_C^{LDA} is the LDA functional for correlation energy. E_C^{nl} is obtained using a relatively simple double space integration.

3. Results and discussion

Determining correct structural properties of materials is essential for the analysis of their other properties, such as the bandgap of semiconductors.³⁴ To compare the performance of various functionals, the structures of organic/inorganic hybrid perovskite CH₃NH₃PbI₃ crystals are firstly optimized. The initial lattice constants and atomic coordinates of orthorhombic CH₃NH₃PbI₃ crystals for theoretical optimizations are from the X-ray diffraction (XRD) experiments at 100K.¹⁵ The optimized lattice constants and volumes using the various functionals are listed in Table 1 with the available experimental values.¹⁴⁻¹⁵ In general, the PZ81/LDA functional underestimates all the lattice constants, while PBE/GGA functional overestimates them.³⁵ The

deviations of volumes of PZ81 and PBE are larger than 6.0%. The variations of the theoretical lattice constants using PZ81 and PBE are close to those of other solids using similar functionals.³⁶ In our calculation, the best structural descriptions are obtained with the non-local optB86b+vdWDF functional. The deviation with respect to the experimental data is less than 1.0%. To detect the origin of the improvement, we also calculate the structural properties of orthorhombic CsPbI_3 crystals, as listed in Table 1. It can be found that properties determined using PBE/GGA and optB86b + vdWDF methods are similar as that of orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$.³⁷ Considering that the main difference between CsPbI_3 and $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystals are the cations. Thus, the significant improvement on the calculation accuracy of the orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystals demonstrates that the weak vdW binding between the organic components across the inorganic framework is required to depict the structural properties for this type of organic/inorganic hybrid materials. This conclusion is different from the assumption used in the recent theoretical studies on organic/inorganic hybrid tetragonal perovskite materials.³⁸ The optimized atomic structure of the orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystals using the optB86b+vdWDF functional is shown in Fig. 1.

The structures from the XRD refinement experiments show angular distortions of the $[\text{PbI}_6]$ octahedra,¹⁵ such as Γ anions have a significant transverse displacement from the mid-point of the Pb-Pb distance to which they are constrained in the ideal crystallographic description (see Fig. 1). The displacements of atoms cause a reduction in symmetry of the $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystal from the cubic phase to the orthorhombic phase. Table 2 lists the theoretical displacement parameters of Pb1, I1 and I2 atoms, marked in Fig. 1, using various functionals compared with the experimental data. The displacement parameters are the differences of the fractional coordinates of atoms between optimized structures and ideal crystallographic structures. It can be seen that most of the theoretical displacement parameters are in very good agreement with the experimental values, except the displacement of I1 atoms along the c direction.¹⁵ Also, the

**Fig. 2** Total density of states (TDOS) of orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystals and their bandgap energies using different functionals.

displacements of the I1 atoms in a and c directions are larger than those of the I2 atoms. The I2 atoms shift more along the b direction. The Pb-I1-Pb angle is about 159° in optB86b+vdWDF results, which is 11° larger than the Pb-I2-Pb angle. These structural differences indicate that I1 and I2 atoms are inequivalent atoms.

Since the organic/inorganic hybrid perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$ materials are used as light harvesters in DSCs,^{4-6, 10} their electronic structures are crucial factors for sunlight absorption. In this regard, the total density of states (TDOS) is calculated using the various functionals (see Fig. 2). In our calculations, the bandgap energy with the PZ81/LDA functional is 1.51 eV, which is 17.9% less than that with the PBE/GGA functional. Our bandgap energy of the PBE/GGA functional is ca. 10% larger than the previous theoretical value.¹⁵ This is because the lattice constants used in our study are 8.0% larger than the previous one, in which the experimental lattice constants were used. Our results support the strong relationship between structural properties and bandgap energies, and highlight the importance of using approximations which accurately reproduce the correct geometry.³⁴ When the optB86b+vdWDF functional is employed, the theoretical bandgap energy is 1.74 eV, which is ca. 0.1 eV smaller than that with the PBE functional. This difference can also be ascribed to the different theoretical lattice constants given by various functionals. According to the optical absorption experiments, the electronic bandgap of orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystals is 1.68 - 1.72 eV at low temperature.³⁹⁻⁴⁰ Consequently, the experimental bandgap energies of hybrid $\text{CH}_3\text{NH}_3\text{PbI}_3$ are surprisingly close to the theoretical predictions at the semi-local and non-local level. Previous DFT studies demonstrate that the bandgap energies of solid-state semiconductors are seriously underestimated by using pure DFT functionals. In some cases, the deviation is about 30%.⁴¹⁻⁴² This is because good band gaps are not normally to be expected from functionals of the types tested here, which do not have hybrid characters.⁴²⁻⁴⁴ This successful match is likely to be fortuitous, which is also observed in other Pb-based materials.^{15, 38, 45} Fig. 2 also shows that that the characteristics of peaks using various functionals in TDOS images are broadly similar, except for the locations of the peaks.

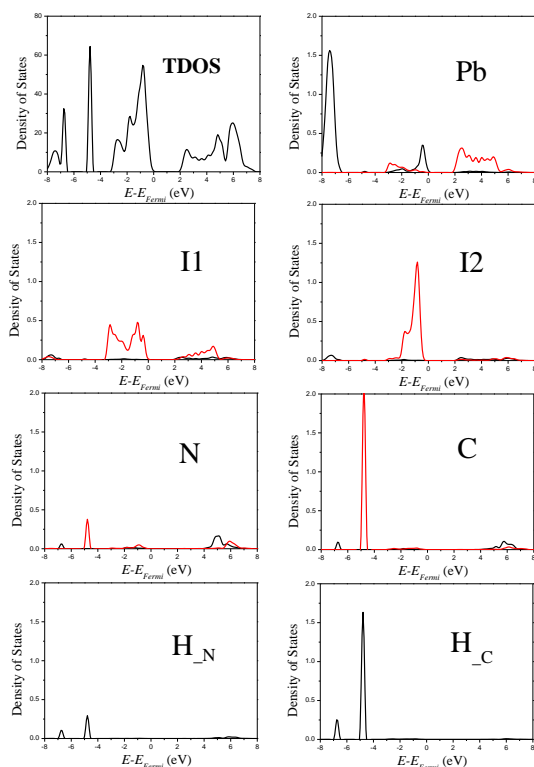

Fig. 3 TDOS and Partial density of states (PDOS) of atoms in orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystals using the optB86b+vdWDF functional. The black and red lines are for s and p states, respectively.

To understand the bonding mechanisms between the atoms, the analysis of partial density of states (PDOS) has been performed. The calculations of TDOS reveal that the functionals have small effects on the main characteristics of peaks. Therefore, only the analysis of PDOS using the optB86b+vdWDF functional is shown in Fig. 3. The PDOS images of I1 and I2 supports the argument that these two kinds of I atoms are chemically inequivalent. The PDOS peaks of I2 atoms are closer to the Fermi energy and sharper than those of I1 atoms in the top valence bands. The stronger hybridization of the orbitals can shift the location of valence bands to the lower energy area with wider peaks.⁴⁶ Thus, the different PDOS images of I1 and I2 atoms indicate a weaker bonding between Pb and I2 atoms. From Fig. 3, organic CH_3NH_3^+ cations have little contribution to the top valence and bottom conduction bands around the Fermi energy level ($-4.0 \text{ eV} < E-E_{\text{Fermi}} < 4.0 \text{ eV}$). The main contribution to the top valence band is from the I 5p states with an overlapping of Pb 6s states. In the bottom conduction bands, the main components are Pb 6p states. The PDOS images suggest that I 5p electrons, especially the I2 5p electrons, can be photo-excited to Pb 6p empty states. Consequently, I atoms change into photohole sites and Pb atoms hold the photoelectrons after the photo-excitation. From Fig. 3, we also find that the highest C and N 2p bands and H 1s bands locate at -6.8 and -4.8 eV , which has little overlap with the Pb and I orbitals. Thus, there is no covalent interaction between the organic cations and the inorganic Pb-I framework.

The band structures of orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$ using

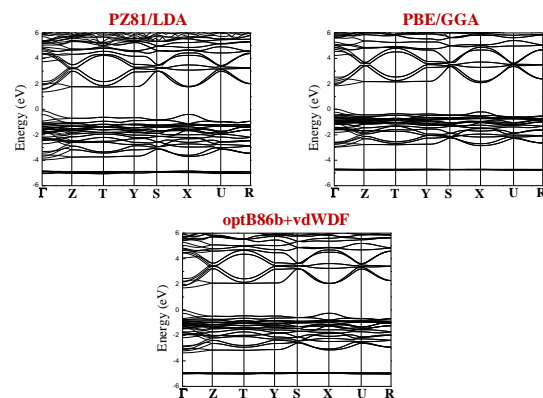

Fig. 4 Calculated band structure of orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystals along the high-symmetry lines in the first Brillouin zone using PZ81/LDA, PBE/GGA, and optB86b+vdWDF functionals, respectively.

different functionals are shown in Fig. 4. Our results agree with previous studies in showing that the orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$ is a direct-bandgap crystal with the minimum band gap at the Γ symmetry point.¹⁵ The minimum indirect bandgap is from the Γ point to the X point. For all band structures, several sets of bands can be found. They correspond to C 2p and H_{C} (the H atoms bonded to C atoms) 1s states around -5 eV , mainly I 5p states below the Fermi level, and Pb 6p states above the Fermi level. Both the top valence band and the bottom conduction band are broad, indicating these states are non-localized. This explains why the excitons can be transported long distance in this material.¹¹⁻¹² Moreover, the fluctuations of the states in the bottom conduction band are stronger, indicating a faster transport of photoelectrons that matches the experimental observations.¹² On the contrary, the band for organic fragments (the band around -5 eV) is flat and narrow, suggesting that the electrons around them are localized. It should also be noted that the band structure of the orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystal is quite different from that of cubic phase due to the lower symmetry and bigger primitive cell. The main functional dependent properties are the locations of the bands, which confirm the conclusion from the analysis of DOS images.

The Bader charges of Pb, I1, I2, N and C atoms in the

orthorhombic perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$ crystals based on the pseudo valence density using different functionals are listed in Table 3. In general, the charge analysis provides a picture of ionic interactions between inorganic Pb-I framework and organic CH_3NH_3^+ cations since the average charge per PbI_3 and CH_3NH_3 unit is ca. $-0.7 e$ and $+0.7 e$. On the contrary, charges of Pb and I atoms correspond to significant deviations from purely ionic interactions (i.e., Pb^{2+} and I^-), which suggests a combined covalent and ionic bonding mechanism between Pb and I atoms. The Pb-I covalent bonding characteristics can also be supported by the hybridization of the Pb 6s, 6p states with the I 5p states at the top valence bands shown in Fig. 3. Within CH_3NH_3^+ cations, the NH_3 group is almost charge neutral; and most of positive charge is the contribution from the CH_3 group. This charge distribution matches the chemical instinct because NH_3 is a charge neutral molecule and CH_3 is a positively charge cation in the gas phase. The charge distribution shown in Table 3 indicates that there is a slightly stronger ionic interaction between CH_3 group and I atoms. From the PDOS analysis, there is a stronger Pb-I covalent bonding. Thus, I atoms have overall stronger interactions with their adjacent atoms, which explains why I1 and I2 atoms are chemically inequivalent, as observed in Fig. 3. In the tetragonal and cubic phase, the symmetries of Pb-I frameworks are improved due to the thermal movement of organic cations. In those cases, the inequivalence of I atoms may be eliminated. A study on the thermal effect on the phase change and properties of $\text{CH}_3\text{NH}_3\text{PbI}_3$ materials is currently under way. Since the charge analysis using the all-electron (AE) reconstructed valence density could give more accurate results,⁴⁷ the calculations based on the AE data with optB86B+vdWDF are also performed, as listed in Table 3. It can be seen that conclusions drawn from both sets of data are almost identical. The main difference is the charge of N atoms and the H atoms bonded with N atoms.

4. Conclusions

In summary, first principle DFT calculations have been performed to study structural and electronic properties of orthorhombic perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$ materials. Our results demonstrate that the employment of optB86B+vdWDF XC functional improves the accuracy of the calculated structural properties significantly compared with the non-vdW functionals employed here. Thus, consideration of the vdW interaction is important for theoretical studies of this organic/inorganic hybrid material. The main interaction between the organic groups and inorganic framework is through the ionic binding between CH_3^+ cations and I^- anions. The different interaction strengths between I atoms with their adjacent atoms cause the formation of two kinds of I atoms in the Pb-I framework. Analysis of the electronic properties supports the conclusion that orthorhombic $\text{CH}_3\text{NH}_3\text{PbI}_3$ is a direct-bandgap crystal with the minimum band gap at the Γ symmetry point. During light harvesting, I 5p electrons can be photo-excited to Pb 6p empty states. Our results, therefore, pave a way for the further theoretical studies on this type of organic/inorganic hybrid perovskite materials for sensitized solar cells.
