Heterogeneous Cellular Networks Using Wireless Backhaul: Fast Admission Control and Large System Analysis

Jian Zhao, Member, IEEE, Tony Q. S. Quek, Senior Member, IEEE, and Zhongding Lei, Senior Member, IEEE

Abstract

We consider a heterogeneous cellular network with densely underlaid small cell access points (SAPs). Wireless backhaul provides the data connection from the core network to SAPs. To serve as many SAPs as possible with guaranteed data rates, admission control of SAPs needs to be performed in wireless backhaul. Such a problem involves joint design of transmit beamformers, power control, and selection of SAPs. In order to tackle such a difficult problem, we apply $\ell_1$-relaxation and propose an iterative algorithm for the $\ell_1$-relaxed problem. The selection of SAPs is made based on the outputs of the iterative algorithm. This algorithm is fast and enjoys low complexity for small-to-medium sized systems. However, its solution depends on the actual channel state information, and resuming the algorithm for each new channel realization may be unrealistic for large systems. Therefore, we make use of random matrix theory and also propose an iterative algorithm for large systems. Such a large system iterative algorithm produces asymptotically optimum solution for the $\ell_1$-relaxed problem, which only requires large-scale channel coefficients irrespective of the actual channel realization. Near optimum results are achieved by our proposed algorithms in simulations.

I. INTRODUCTION

Fifth Generation (5G) mobile communication networks are expected to provide ubiquitous ultra-high data rate services and seamless user experience across the whole system [1], [2], which makes
it necessary to offload huge volumes of data from macrocells to small cells. In 5G networks, hyper-
dense deployment of small cells will be a key factor to achieving better spatial resource reuse and
tremendous capacity enhancement to macrocells. The services of small cells are provided by small
cell access points (SAPs), which are low power nodes only serving local-area users. In order to
obtain the small cell user data, the SAPs are connected to the core network via backhaul.

As large numbers of small cells are underlaid with macrocells and more data traffic is diverted
from macrocells to small cells, providing fast and reliable backhaul connection between the core
network and SAPs becomes a critical issue for such multi-tier heterogeneous networks [3], [4].
Wired backhaul, which uses copper or fiber cables, can provide high-rate data links between fixed
stations. However, the cost to provide wired backhaul to all SAPs may be prohibitive when the
number of SAPs is large. Moreover, certain locations that are difficult to be reached by wired access
may restrict the universal deployment of wired backhaul. Wireless backhaul, which can overcome
many of the drawbacks of wired backhaul, offers a cost-effective alternative [5]–[8]. Combined
with renewable energy sources, SAPs with wireless backhaul can be established in a self-sustained
“drop-and-play” fashion, which is especially important in countries lacking reliable and ubiquitous
power supply [1]. Compared to wired backhaul, the management of wireless backhaul resources,
e.g., power and spectrum, is more complicated due to finite power and radio spectrum constraints.

Recent works have proposed analysis and design methods for backhaul technologies from many
aspects. A linear programming framework for determining optimum routing and scheduling of
data flows in wireless mesh backhaul networks was proposed in [9]. Zhao et al. [10] considered
the problem of minimizing backhaul user data transfer in multicell joint processing networks.
Algorithms involving joint design of transmit beamformers and user data allocation at base stations
(BSs) were proposed to efficiently reduce the backhaul user data transfer. Zhou et al. [11] presented
an information-theoretical study of an uplink multicell joint processing network in which the BSs
are connected to a centralized processing server via rate-limited digital backhaul links employing
the compress-and-forward technique. A similar scenario for the downlink of a cloud radio access
network (Cloud-RAN) was investigated in [12], where multivariate compression of different BSs’
signals was exploited to combat additive quantization noise. The spectral efficiency and energy
efficiency tradeoff in a homogeneous cellular network was investigated in [13], where the backhaul
power consumption was taken into consideration. Considering the overall network power consump-
tion including the backhaul, Shi et al. [14] proposed schemes to improve the energy efficiency in
Cloud-RAN cellular networks. For the Cloud-RAN backhauling, not only the routing of data but
also the additional cost of baseband processing in the cloud infrastructure has been investigated in
[12], [14]. Wireless backhaul technologies have been discussed in [5]–[8]. Hur et al. [5] proposed
a beam alignment technique for millimeter wave wireless backhaul and investigated the tradeoff

...
between array size and wind-induced movement. Lee et al. [6] provided several admission control schemes for multihop wireless backhaul network under rate and delay requirements. Flexible high-capacity hybrid wireless and optical mobile backhauling for small cells was investigated in [7]. The energy efficiencies of wireless backhaul networks for different system architectures and frequency bands were compared in [8].

A vital task of wireless communications is to design schemes to meet the quality-of-service (QoS) requirements subject to given amount of resources. Resource management of wireless systems with QoS requirements has been discussed in [15]–[19]. A decentralized method to minimize the sum transmit power of BSs under given QoS requirements was proposed in [15] for a multicell network, relying on limited backhaul information exchange between BSs. Iterative algorithms to maximize the minimum QoS measure of users in multicell joint processing networks under per-BS power constraints were proposed in [16]. When it is not possible to meet the QoS requirements for all wireless stations with the given resources, only a subset of transmission links can be selected to be active. Zhai et al. [17] investigated the link activation problem in cognitive radio networks with single-antenna primary and secondary BSs and users. A price-driven spectrum access algorithm was proposed and the energy-infeasibility tradeoff was analyzed. The uplink user admission control and user clustering under given QoS and power constraints were considered in [18], where algorithms relying on the $\ell_1$-norm relaxation were proposed. Transmission schemes using semidefinite relaxation and Gaussian randomization to select active antenna ports were proposed in [19] to maximize the minimum user rate in multicell distributed antenna systems.

In order to achieve enormous enhancement in spectral efficiency, the technique of “massive multiple-input multiple-output (MIMO)” is envisioned to be an important ingredient in 5G communication systems [20], [21]. In massive MIMO, the number of antennas equipped at BSs is much larger than that of active users in the same time-frequency channel. Hoydis et al. [22] analyzed the number of required antennas in massive MIMO systems using different linear beamformers. They showed that more sophisticated beamformers may reduce the number of required antennas in massive MIMO systems to achieve the same performance. Fernandes et al. [23] provided the asymptotic performance analysis of both the downlink and the uplink for a cellular network as the number of BS antennas tends to infinity. Huang et al. [24] studied joint beamformer design and power allocation in multicell massive MIMO networks, where efficient algorithms to maximize the minimum weighted QoS measure of all the users were proposed.

In this paper, we consider a heterogeneous cellular network with densely underlaid single-antenna SAPs. The core network are connected to the SAPs via wireless backhaul links, which provide the channel to transfer the small cell user data. A wireless backhaul hub (WBH) with multiple antennas is deployed to transmit wireless backhaul signals to the SAPs. Minimum data rate requirements
must be satisfied when SAPs receive data from the WBH so that small cell users can be served at the required data rates. To offload macrocell users and divert data traffic from the macrocell to small cells, as well as to minimize the total cost of building backhaul in the network, it is desirable for the WBH to support as many SAPs as possible. Given QoS constraints at SAPs and power constraint at the WBH, we propose wireless backhaul transmission schemes aiming to admit the maximum number of SAPs into the network. Such transmission schemes involve joint design of beamformers and power control, as well as selection of subset of SAPs to be supported. We tackle this difficult problem by applying $\ell_1$-norm relaxation to the original non-convex non-smooth problem and utilize uplink-downlink duality to transform the transmit beamforming problem into an equivalent receive beamforming problem. Based on the optimality conditions, we propose an iterative algorithm that jointly update the values of the primal and dual variables. Such an algorithm is fast and we prove that it converges locally to the optimum solution. Based on the solution of the $\ell_1$-relaxed problem, we then iteratively remove the SAP that corresponds to the largest QoS gap until all the remaining SAPs can be supported. Furthermore, we provide a large system analysis of the above SAP admission control problem. As the system dimensions become large, we show that certain system parameters may be approximated as deterministic quantities irrespective of the actual channel realization. Random matrix theory is leveraged to transform our proposed finite system iterative algorithm for large systems so that only large-scale statistical information of the channel is required. As long as the large-scale channel coefficients and the QoS requirements remain unchanged, the selected SAPs will satisfy the QoS and power constraints almost surely. Simulations are carried out to verify the proposed algorithms for finite and large systems. The proposed algorithms demonstrate fast convergence and low computational complexity. For the finite system iterative algorithm, the average number of admitted SAPs is very close to the optimum results. For the large system iterative algorithm, the results of the selected SAPs accurately match those obtained by Monte Carlo simulations.

The remainder of the paper is organized as follows. In Section II, we introduce the system model and formulate the SAP admission control problem. The iterative algorithm for finite systems and its convergence property are presented in Section III. The large system analysis and its corresponding iterative algorithm are presented in Section IV. Section V shows the convergence behavior and the simulation results in a cellular scenario. Finally, conclusions are drawn in Section VI.

Notation: we use bold uppercase letters to denote matrices and bold lowercase letters to denote vectors. $CN(0, \sigma^2)$ denotes a circularly symmetric complex normal zero mean random variable with variance $\sigma^2$. $(\cdot)^T$ and $(\cdot)^H$ stand for the transpose and conjugate transpose, respectively. $\mathbb{C}^M$ and $\mathbb{R}^M_+$ denote $M$-dimensional complex vectors and nonnegative real vectors, respectively. $E\{\cdot\}$ stands for the mathematical expectation. $\{u_i\}$ denotes the set made of $u_i, \forall i$. $\|x\|, \|x\|_0$ and $\|x\|_1$ stand for
the Euclidean norm, the $\ell_0$-norm and the $\ell_1$-norm of the vector $x$, respectively. $\xrightarrow{a.s.}$ denotes almost sure convergence. $\rho(A)$ stands for the spectral radius of matrix $A$. $a \circ b$ denotes the Hadamard product of $a$ and $b$. For a vector $q$, $q^{-1}$ stands for the element-wise inverse of $q$.

II. SYSTEM MODEL AND PROBLEM FORMULATION

We consider a heterogeneous cellular network with $N$ underlaid single antenna SAPs as in Fig. 1. The SAPs obtain their small cell user data from the core network via wireless backhaul. A WBH with $M$ antennas is responsible for transmitting wireless backhaul signals to the SAPs. The wireless backhaul spectrum is out-of-band, which does not interfere with users in the network. In order to meet the data rate requirements for serving small cell users, the received data at the SAPs must satisfy certain minimum rate requirements. In a heterogeneous cellular network, users that cannot be served by SAPs will have to be served by the macrocell base station (MBS) directly. In order to let more users be served by the SAPs and divert the data traffic from the macrocell to small cells, as well as to minimize the total cost of building backhaul in the network, it is desirable for the WBH to support as many SAPs as possible. Given QoS requirements at SAPs and wireless backhaul power constraint at WBH, we propose schemes that admit the maximum number of SAPs that can be simultaneously supported by the WBH using wireless backhaul.

We denote the wireless backhaul channel from the WBH to the $i$th SAP as $h_i^H$, where $h_i \in \mathbb{C}^M$, $\forall i = 1, \cdots, N$. Linear transmit processing is applied at the WBH to deliver user data to the SAPs using wireless backhaul links. The transmit beamformer at the WBH for the $i$th SAP is denoted as $u_i \in \mathbb{C}^M$, such that $\|u_i\| = 1$, $\forall i$. We denote the normalized data symbol for the $i$th SAP’s users that is transmitted via wireless backhaul as $d_i$, where $E\{|d_i|^2\} = 1$. The received signal at the $i$th SAP can be expressed as

$$y_i = h_i^H u_i \sqrt{\frac{p_i}{M}} d_i + \sum_{j=1, j \neq i}^{N} h_i^H u_j \sqrt{\frac{p_j}{M}} d_j + \eta_i$$

(1)
where $\eta_i$ is the additive white Gaussian noise (AWGN) at the $i$th SAP, such that $\eta_i \sim \mathcal{CN}(0, n_i)$ and $n_i$ denotes the noise variance. The transmit power for data of the $i$th SAP is $p_i/M$. We denote the power constraint for backhaul transmission at the WBH as $P$. The backhaul transmit power must satisfy $\sum_{i=1}^{N} w_i p_i / M \leq P$, where $w_i > 0$ is the weight for the $i$th transmit power. The signal to interference-plus-noise ratio (SINR) at the $i$th SAP is given by

$$\text{SINR}_i^D = \frac{\frac{p_i}{M} |h_i^H u_i|^2}{\sum_{j=1,j\neq i}^{N} \frac{p_j}{M} |h_i^H u_j|^2 + n_i}. \quad (2)$$

In order to meet the QoS requirements of its small cell users, the receive SINR at each SAP must satisfy minimum SINR requirement. The SINR requirements at SAPs can be determined from the QoS requirements of their small cell users and they can be easily fed back to the core network. We denote the SINR requirement for the $i$th SAP as $\gamma_i$, $\forall i$.

In heterogeneous networks, small cells are deployed within the macrocell to serve users so that the number of users needed to be served by the MBS can be reduced to the minimum. When the SAPs are densely deployed, the WBH may not be able to support all the SAPs simultaneously for given SINR and power constraints. The users that cannot be served by SAPs need to be served by the MBS. In order to let more users be served by the SAPs and divert the data traffic from the macrocell to small cells, it is desirable to select the subset of SAPs with the maximum cardinality that can be simultaneously supported by the wireless backhaul. In this way, we also minimize the total cost of building backhaul to small cells in the network. Such a problem of SAP admission control can be formulated as

$$\min_{\{p_i, x\} : \mathbf{x}} \|\mathbf{x}\|_0 \quad \text{s.t.} \quad \text{SINR}_i^D \geq \frac{\gamma_i}{1 + x_i}, \quad \forall i = 1, \ldots, N,$$

$$\frac{1}{M} \mathbf{w}^T \mathbf{p} \leq P,$$

$$\mathbf{x} \geq 0$$

where $\mathbf{w} = [w_1, \ldots, w_N]^T$, $\mathbf{p} = [p_1, \ldots, p_N]^T$, and $\mathbf{x} = [x_1, \ldots, x_N]^T \in \mathbb{R}_+^N$. Here $x_i \geq 0$ represents the SINR gap of the $i$th SAP to satisfy its SINR requirement. If $x_i = 0$ in the solution, it shows that the SINR requirement $\gamma_i$ can be satisfied by the $i$th SAP. The objective function $\|\mathbf{x}\|_0$ denotes the $\ell_0$-norm of $\mathbf{x}$, which is the number of non-zero elements in $\mathbf{x}$.

$^1$Denote the users of the $i$th small cell as $J_i$. Assume the data rate requirement of the $i$th user to be $r_i$, $\forall i \in J_i$. Then, the SINR requirement for the $i$th SAP must be chosen such that $\log_2(1 + \gamma_i) \geq \sum_{j \in J_i} r_j$. Notice that after the QoS requirements of SAPs are determined and fed back to the core network, existing coordinated multipoint (CoMP) transmission strategies can be applied for the communication from the SAPs to the users. The transmission strategies from the SAPs towards the users are independent of the wireless backhaul transmission from the core network to the SAPs. Therefore, we do not discuss the transmission schemes from the SAPs to the users in this paper.
III. ANALYSIS AND ALGORITHM DESIGN FOR FINITE SYSTEMS

The problem (3) is combinatorial and NP-hard due to the non-convex $\ell_0$-norm in the objective function [25]. Approximate solutions of non-convex optimization problems can be obtained by applying convex relaxation [10], [18] and replacing the $\ell_0$-norm in (3) with its convex envelop, i.e., the $\ell_1$-norm. The $\ell_1$-relaxed problem can then be expressed as

$$\min_{p, \{u_i\}, x} \|x\|_1$$

s.t. constraints of (3).  

The problem (4) is still difficult to solve due to the need to jointly optimize the transmit power $p$, transmit beamformers $\{u_i\}$, and the SINR gap $x$. The following lemma shows that the downlink transmit optimization problem (4) can be converted to an uplink receive optimization problem.

**Lemma 1:** The downlink transmit optimization problem (4) is equivalent to the following dual uplink receive optimization problem

$$\min_{q, \{u_i\}, x} \sum_i x_i$$

s.t. $\text{SINR}_i^U \geq \frac{\gamma_i}{1 + x_i}, \forall i = 1, \cdots, N,$

$$\frac{1}{M} n^T q \leq P,$$

$$x \geq 0$$

where $n = [n_1, \cdots, n_N]^T$ and $q = [q_1, \cdots, q_N]^T \in \mathbb{R}^N_+$. Here we define

$$\text{SINR}_i^U = \frac{\frac{q_i}{M} |u_i^H h_i|^2}{\sum_{j=1,j\neq i}^N \frac{q_j}{M} |u_j^H h_j|^2 + w_i}.$$  

Furthermore, the optimum solution of $\{u_i\}$ and $x$ are the same in (4) and (5). The optimum solution of $p$ in (4) has one-to-one correspondence to the optimum solution of $q$ in (5). The problem (5) is a receive optimization problem in the dual uplink with the same SINR constraints, where $h_i$ is the dual uplink channel from the $i$th SAP to the WBH and $w_i$ becomes the uplink noise variance at the $i$th SAP. Here $q_i/M$ represents the dual uplink transmit power of the $i$th SAP, and $u_i^H$ is the uplink receive beamformer for the $i$th SAP transmission.

**Proof:** See Appendix A.

We denote the optimum solution of (4) as $p^*$, $\{u_i^*\}, x^*$. According to Lemma 1, the optimum solution of (5) can be denoted as $q^*$, $\{u_i^*\}, x^*$. The following lemma shows that the optimum beamformer $\{u_i^*\}$ can be determined from the optimum uplink power $q^*$.

**Lemma 2:** The optimum receive beamformer $\{u_i^*\}$ of (5) is the minimum mean square error (MMSE) receiver, which can be obtained from the optimum uplink power $q^*$ as

$$u_i^* = u_i^\text{MMSE}(q^*) = \frac{1}{\xi} \left( \sum_{j=1,j\neq i}^N \frac{q_j^*}{M} h_j^H h_j + w_i I \right)^{-1} h_i, \forall i = 1, \cdots, N$$

(7)
where $\xi$ is a normalization factor such that $\|u_\star_i\| = 1$. The corresponding uplink SINR in (6) is

$$\text{SINR}_U(i, \{u_\star_i\}) = \frac{q_\star_i h_i H}{M} \left( \sum_{j=1, j \neq i}^N \frac{q_\star_j h_j h_j H + w_i I}{M} \right)^{-1} h_i, \quad \forall i. \quad (8)$$

Proof: See Appendix B.

For notational brevity, we define an equivalent channel matrix $G$, where

$$G_{ij} = \left| h_i^H u_j \right|^2, \quad \forall i, j = 1, \cdots, N \quad (9)$$

and we omit the dependence of $G_{ij}$ on $u_j$. After a change of variables $q_\star_i = \log(q_\star_i M)$, $\forall i$, the problem (5) can be equivalently expressed as

$$\min_{\tilde{q}, \{u_i\}, x} \sum_i x_i$$

$$\text{s.t.} \quad \log \frac{\gamma_i \left( \sum_{j=1, j \neq i}^N G_{ij} e_{\tilde{q}_j} + w_i \right)}{G_{ii} e_{\tilde{q}_i}} \leq \log(1 + x_i), \quad \forall i = 1, \cdots, N \quad (10)$$

$$\sum_{i=1}^N n_i q_\star_i \leq P, \quad x \geq 0.$$

For fixed $\{u_i\}$, the problem (10) is a geometric programming (GP) problem whose solution in $\tilde{q}$ and $x$ can be obtained by standard convex optimization software [26]. Considering $\{u_i\}$ as optimization variables, one method to obtain solutions of (10) is alternately optimizing $\{q, x\}$ and $\{u_i\}$ by solving (10) with fixed $\{u_i\}$ and updating the MMSE receiver $\{u_i^{\text{MMSE}}\}$ using the obtained $q$, respectively. However, this method is slow and has high computational complexity. In the following, we provide a low complexity iterative algorithm.

We associate the $i$th SINR constraint in (10) with the Lagrange dual variable $\nu_i$, the power constraint with $\mu$, and the nonnegativity constraint of $x_i$ with $\alpha_i$. The GP problem (10) satisfies Slater’s condition. Hence, the Karush-Kuhn-Tucker (KKT) conditions are necessary and sufficient for the optimality of (10). The following theorem provides the optimality conditions for (10), which is key to our iterative algorithm that solves (4).

**Theorem 1**: The optimum primal and dual solutions of (10) satisfy the following conditions

$$x_\star_i = \max \left( \nu_\star_i - 1, 0 \right), \quad \forall i = 1, \cdots, N; \quad (11)$$

$$\frac{M \nu_\star_i}{q_\star_i} = \sum_{j=1, j \neq i}^N \frac{M G_{ij} \gamma_j \nu_\star_j}{(1 + x_\star_j) G_{jj} q_\star_j} + \mu \star n_i, \quad \forall i; \quad (12)$$

$$\frac{(1 + x_\star_i) G_{ii} q_\star_i}{M \gamma_i} = \sum_{j=1, j \neq i}^N \frac{G_{ji} q_\star_j}{M} + w_i, \quad \forall i; \quad (13)$$

$$\sum_{i=1}^N n_i q_\star_i = P; \quad (14)$$

$$\mu \star > 0; \quad \nu_\star_i > 0, \quad \forall i. \quad (15)$$
The optimum downlink power $p^\star_i$ of (4) can be obtained directly from the optimum primal and dual solutions of (10) as
\[ p^\star_i = \frac{M \gamma_i \nu^\star_i}{(1 + x^\star_i) G_{ii} q^\star_i \mu^\star_i}, \quad \forall i. \] (16)

Furthermore, we have
\[ \frac{(1 + x^\star_i) G_{ii} p^\star_i}{M \gamma_i} = \sum_{j=1, j \neq i}^{N} \frac{G_{ij} p^\star_j}{M} + n_i, \quad \forall i; \] (17)
\[ \sum_{i=1}^{N} w_i p^\star_i = P. \] (18)

**Proof:** See Appendix C.

**Corollary 1:** The optimum downlink transmit power $p^\star$ of (4) and the optimum primal and dual solutions of (10) satisfy
\[ \nu^\star_i = \left( \sum_{j=1, j \neq i}^{N} \frac{G_{ij} p^\star_j}{M} + n_i \right) \frac{\mu^\star q^\star_i M}{1 + x^\star_i}, \quad \forall i = 1, \ldots, N; \] (19)
\[ \mu^\star = \sum_{i=1}^{N} \frac{M \gamma_i \nu^\star_i w_i}{(1 + x^\star_i) G_{ii} q^\star_i P}; \] (20)
\[ \frac{\gamma_i}{(1 + x^\star_i)} = \text{SINR}^U_{\nu_i} (q^\star, \{u^\star_i\}) = \frac{q^\star_i}{M} h_i^H \left( \sum_{j=1, j \neq i}^{N} \frac{q^\star_j}{M} h_j h_j^H + w_i I \right)^{-1} h_i, \quad \forall i. \] (21)

Here (19) is obtained by substituting (16) into (12). Eq. (20) is obtained by substituting (16) into (18). Eq. (21) is obtained by (13) and Lemma 2.

Based on Theorem 1 and Corollary 1, we propose Algorithm 1 that iteratively updates the values of the primal and dual variables to obtain the optimum $p^\star$, $\{u^\star_i\}$ and $x^\star$ of (4). In Algorithm 1, we first store the old values of $q$ in (22). The fixed-point iteration (23) and normalization (24) are obtained according to (21) and (14), respectively. Here (25) is to ensure contraction mapping for the algorithm, which will be made clear in the proof of Theorem 2. After obtaining the uplink power $q$, we calculate the corresponding MMSE receiver and the equivalent channel in (26) and (27) according to (7) and (9), respectively. The value of $\mu$ in (28) is obtained according to (20). The corresponding downlink power (29) is calculated according to (16) after getting the value of $\mu$, and the value of $\nu_i$ in (30) is updated according to (19). In this algorithm, the optimum solution of $p^\star$ is obtained directly in (29). There is no need to perform the uplink-downlink power mapping (27). The convergence property of Algorithm 1 is shown in the following theorem.

**Theorem 2:** Starting from an initial point that is sufficiently close to the optimum solution of (5), Algorithm 1 converges to the optimum solution of (5) that satisfies the KKT conditions.

**Proof:** See Appendix D.
Algorithm 1 Finite system iterative algorithm to solve (4)

1: Initialization: $\nu_i \geq 1$ and $q_i > 0$, $\forall i$, such that $\sum_{i=1}^{N} n_i q_i = MP$.
2: repeat
3: Store old values of $q$
   \[ \tilde{q} = q. \] \(\text{(22)}\)
4: Update
   \[ \bar{q}_i = \frac{M \gamma_i}{\max(\nu_i, 1) \cdot \left( h_i^H \left( \sum_{j=1, j\neq i}^{N} \frac{q_j}{M} h_j h_j^H + w_i I \right)^{-1} h_i \right)}, \quad \forall i = 1, \cdots, N. \] \(\text{(23)}\)
5: Normalize
   \[ \bar{q} = \frac{MP}{n^T \bar{q}} \bar{q}. \] \(\text{(24)}\)
6: Set
   \[ q = \frac{1}{2} (\bar{q} + \tilde{q}). \] \(\text{(25)}\)
7: Calculate $u_i$
   \[ u_i = \frac{1}{\xi} \left( \sum_{j=1, j\neq i}^{N} q_j^* \bar{h}_j \bar{h}_j^H + w_i I \right)^{-1} \bar{h}_i, \quad \forall i. \] \(\text{(26)}\)
8: Calculate the equivalent channel
   \[ G_{ij} = |h_i^H u_j|^2, \quad \forall i, j = 1, \cdots, N. \] \(\text{(27)}\)
9: Calculate $\mu$
   \[ \mu = \sum_{i=1}^{N} \frac{M \gamma_i \nu_i w_i}{\max(\nu_i, 1) \cdot G_{ii} q_i P}. \] \(\text{(28)}\)
10: Calculate the downlink power
    \[ \frac{p_i}{M} = \frac{M \gamma_i \nu_i}{\max(\nu_i, 1) \cdot G_{ii} q_i P}, \quad \forall i. \] \(\text{(29)}\)
11: Update $\nu_i$
    \[ \nu_i = \left( \sum_{j=1, j\neq i}^{N} \frac{G_{ij} p_j}{M} + n_i \right) \frac{\mu q_i}{M}, \quad \forall i. \] \(\text{(30)}\)
12: until $|q_i - \bar{q}_i| \leq \epsilon$, $\forall i$.
13: Set $x_i = \max(\nu_i - 1, 0)$, $\forall i$.
14: return $x$, $p$ and $\{u_i\}$.
Theorem 2 shows that Algorithm 1 converges locally to the optimum solution of (4). However, its range of convergence cannot be obtained from Theorem 2 and the result may depend on the initialization point. Whether this algorithm can converge globally is still an open problem. In our simulations, we observe that its range of convergence is large and even random initialization will converge to correct results.

A. Connections With Max-Min SINR

If all the SAPs can be supported, $x^* = 0$ in the solution of (10). The values of $\nu_i, \forall i$, decrease monotonically towards zero in Algorithm 1. In this case, the update of power in (23)–(24) becomes the power iteration steps in the max-min SINR algorithm of [28]. Algorithm 1 will still converge. The output $p$ and $\{u_i\}$ of Algorithm 1 are the power allocation and beamformers that maximize the minimum SINR of all SAPs in the system.

B. Iterative SAP Removal

Due to the convex relaxation, the solution of (4) may not be always optimal for the $\ell_0$-norm optimization problem (3). Therefore, (4) cannot be simply used as the substitution of (3) and we need to refine the selection of users based on the solution of (4). Since the solution of $x_i$ in (4) represents the gap of the $i$th SAP’s SINR to satisfy its SINR requirement, it is natural for us to select those SAPs with small $x_i$. We propose to iteratively remove SAPs with decreasing values of $x_i$ until the remaining set of SAPs becomes feasible to satisfy the SINR and power constraints, i.e., until $x_i = 0, \forall i$. In this way, we obtain the final results for SAP admission control.

IV. ASYMPTOTIC ANALYSIS AND ALGORITHM DESIGN FOR LARGE SYSTEMS

The algorithm proposed in Section III requires instantaneous channel state information. However, the instantaneous channel state information may change rapidly with time, which can incur frequent resumptions of Algorithm 1 to determine the SAP admission. On the other hand, 5G wireless networks are envisioned to be characterized by large numbers of antennas at WBH and dense deployments of SAPs. Under those circumstances, certain system parameters tend to become deterministic quantities that only depend on large-scale channel statistical information and the QoS requirements at SAPs. The large-scale channel statistical information include pathloss, shadowing and antenna gain, which do not change rapidly with time. The optimum power allocation $p^*$ in (4) and the final selection of SAPs based on $x^*$ will also tend to be deterministic irrespective of the actual channel changes. In the following, we use random matrix theory to provide an iterative algorithm for the SAP admission control problem of large systems. Such an iterative algorithm
solves (4) in the asymptotic optimum sense. As long as the large-scale channel coefficients and the QoS requirements remain unchanged, the selected SAPs using large system analysis will almost surely be the same as the results obtained by the method of Section III based on instantaneous channel state information.

We assume the number of transmit antennas $M$ at WBH and the number of SAPs $N$ go to infinity while the ratio $N/M$ remains bounded, i.e., let $M, N \to \infty$ while $0 < \lim \inf \frac{N}{M} \leq \lim \sup \frac{N}{M} < \infty$. Such an assumption is abbreviated as $M \to \infty$. We use $\overset{a.s.}{\longrightarrow}$ to denote almost sure convergence, where $f(x) \overset{a.s.}{\longrightarrow} a$ means $a$ is the deterministic equivalent of $f(x)$ as $M \to \infty$. The following fading channel model is used for large system analysis

$$h_i = \sqrt{d_i} \tilde{h}_i, \quad \forall i = 1, \cdots, N \quad (31)$$

where $d_i$ represents the large-scale fading coefficient between the WBH and the $i$th SAP. The $\tilde{h}_i$ denotes a normalized channel vector whose elements are independent and identically distributed (i.i.d.) $CN(0, 1)$ random variables.

Under the channel model (31), the uplink SINR (8) using MMSE receive beamformers can be expressed as

$$\text{SINR}^U_i(q, \{u^\text{MMSE}_i\}) = \frac{q_i}{M} h_i^H \left( \sum_{j=1, j \neq i}^{N} \frac{q_j}{M} h_j h_j^H + w_i I \right)^{-1} h_i \quad (32)$$

$$= \frac{q_id_i}{M} \tilde{h}_i^H \left( \sum_{j=1, j \neq i}^{N} \frac{q_jd_j}{M} \tilde{h}_j \tilde{h}_j^H + w_i I \right)^{-1} \tilde{h}_i \forall i. \quad (33)$$

Calculating the uplink SINR (33) involves matrix inversion of dimension $M$, which becomes increasingly complex as $M \to \infty$. However, the following lemma shows that the uplink SINR (33) will tend to deterministic quantities asymptotically. Such deterministic quantities only depend on large-scale fading coefficients $\{d_i\}$ irrespective of the instantaneous channel state information $\{h_i\}$.

**Lemma 3:** As $M \to \infty$, the uplink SINRs (33) using MMSE receive beamformers approach deterministic quantities, i.e.,

$$\text{SINR}^U_i(q, \{u^\text{MMSE}_i\}) \overset{a.s.}{\longrightarrow} q_i d_i \varphi_i(q), \quad \text{as } M \to \infty \quad (34)$$

where

$$\varphi_i(q) = \left( w_i + \frac{1}{M} \sum_{j=1, j \neq i}^{N} \frac{q_jd_j}{1 + q_jd_j \varphi_i(q)} \right)^{-1}, \quad \forall i = 1, \cdots, N. \quad (35)$$

**Proof:** See Appendix F. \qed

The value of $\varphi_i(q)$ is defined implicitly by fixed-point equation (35) and it is deterministic for given $q$.  

Similar to the uplink SINR using MMSE receive beamformers, the equivalent channels of the system using MMSE beamformers also approach deterministic quantities asymptotically. Using the channel model (31), we have
\[
\frac{1}{M} |h_i^H u_j^{\text{MMSE}}|^2 = \frac{d_i}{M} |\tilde{h}_i^H u_j^{\text{MMSE}}|^2, \quad \forall i, j = 1, \ldots, N. \tag{36}
\]
Depending on whether \(i = j\), the equivalent channels approach different deterministic values asymptotically. The following lemma shows the asymptotic equivalent channels when \(i = j\).

**Lemma 4:** As \(M \to \infty\), the equivalent channels \(\frac{1}{M} |h_i^H u_i^{\text{MMSE}}|^2\) using MMSE beamformers approach deterministic quantities, i.e.,
\[
\frac{1}{M} |h_i^H u_i^{\text{MMSE}}|^2 \xrightarrow{a.s.} \frac{d_i \varphi_i^2(\mathbf{q})}{\varphi_i'(\mathbf{q})^2}, \tag{37}
\]
where
\[
\varphi_i'(\mathbf{q}) = -\varphi_i(\mathbf{q}) \cdot \left( w_i + \frac{1}{M} \sum_{j=1, j \neq i}^{N} \frac{q_j d_j}{1 + q_j d_j \varphi_i(\mathbf{q})^2} \right)^{-1}. \tag{38}
\]

**Proof:** See Appendix [G]

The asymptotic equivalent channel when \(i \neq j\) can be obtained by the following lemma.

**Lemma 5:** As \(M \to \infty\), the equivalent channels \(|h_i^H u_j^{\text{MMSE}}|^2\) using MMSE beamformers approach deterministic quantities, i.e.,
\[
|h_i^H u_j^{\text{MMSE}}|^2 \xrightarrow{a.s.} \frac{d_i}{(1 + q_i d_i \varphi_j(\mathbf{q}))^2}, \quad \text{when } i \neq j. \tag{39}
\]

**Proof:** See Appendix [H]

As \(M \to \infty\), we can substitute the deterministic equivalents of the system parameters into Algorithm 1 and obtain an iterative algorithm for large systems that solves (4) as shown in Algorithm 2. Lemma 3 is applied to (23) when updating \(\mathbf{q}\). Lemma 4 is applied to (28) and (29) when updating \(\nu\) and \(p\). Lemma 5 is applied to (30) when updating \(\{\nu_i\}\). Algorithm 2 obtains the asymptotically optimum solutions for \(p^*, q^*\) and \(x^*\) of (4) using MMSE beamformers when \(M \to \infty\). Note the beamformers \(\{u_i^*\}\) do not approach deterministic quantities because their values depend on the actual channel realization. In real system implementations, the outputs of Algorithm 2 can be calculated and stored. Depending on the actual channel state information \(\{h_i\}\), the MMSE beamformers \(\{u_i^*\}\) can be directly obtained using (7). Unlike Algorithm 1 there is no need to resume the algorithm for different channel realizations. In addition, the large-scale fading coefficients of SAPs changes slowly in reality. Algorithm 2 can be re-invoked as soon as the QoS requirements of SAPs change. Therefore, Algorithm 2 can save lots of computation in large systems. After we obtain the output of Algorithm 2 iterative SAP removal can be applied based on the result of \(x\) achieved by Algorithm 2.
Algorithm 2 Large system iterative algorithm to solve (4)

1: Initialization: \( \varphi_i(q) > 0, \nu_i > 0 \) and \( q_i > 0, \forall i \), such that \( \sum_{i=1}^{N} n_i q_i = MP \).

2: repeat

3: Store old values of \( q \)

\[ \tilde{q} = q. \]

4: Update

\[ \tilde{q}_i = \frac{\gamma_i}{\max(\nu_i, 1) \cdot \varphi_i(q) d_i}, \quad \forall i = 1, \ldots, N. \] (40)

5: Normalize

\[ \tilde{q} = \frac{MP}{n \cdot \tilde{q}}. \] (41)

6: Set

\[ q = \frac{1}{2} (\tilde{q} + \bar{q}). \] (42)

7: Update \( \varphi_i(q) \)

\[ \varphi_i(q) = \frac{1}{w_i + \frac{1}{M} \sum_{j=1, j \neq i}^{N} q_j d_j \left( 1 + q_i d_i \varphi_i(q) \right)^2}, \quad \forall i. \] (43)

8: Calculate the corresponding \( \varphi'_i(q) \)

\[ \varphi'_i(q) = \frac{-\varphi_i(q)}{w_i + \frac{1}{M} \sum_{j=1, j \neq i}^{N} q_j d_j \left( 1 + q_i d_i \varphi_i(q) \right)^2}, \quad \forall i. \] (44)

9: Calculate \( \mu \)

\[ \mu = \sum_{i=1}^{N} \frac{-M \nu_i \gamma_i \varphi'_i(q)}{\max(\nu_i, 1) \cdot q_i d_i \varphi^2_i(q) \mu}, \quad \forall i. \] (45)

10: Calculate the downlink power

\[ p_i = \frac{-M \nu_i \gamma_i \varphi'_i(q)}{\max(\nu_i, 1) \cdot q_i d_i \varphi^2_i(q) \mu}, \quad \forall i. \] (46)

11: Update \( \nu_i \)

\[ \nu_i = \left( n_i + \frac{1}{M} \sum_{j=1, j \neq i}^{N} \frac{p_j d_j}{(1 + q_i d_i \varphi_j(q))^2} \right) \frac{\mu q_i}{M}, \quad \forall i. \] (47)

12: until \( |q_i - \tilde{q}_i| \leq \epsilon, \forall i. \)

13: Set \( x_i = \max(\nu_i - 1, 0), \forall i. \)

14: return \( x, p \) and \( q \)
A. Complexity Analysis

For the finite system analysis, the iterative Algorithm 1 needs to perform iterative updates of the primal and dual variables. The most computational intensive steps in the iterations are the steps involving matrix inversion and matrix-vector multiplication in (23) and (26), where each step has the complexity of $O(NM^2 + M^3)$ for each user. Considering all the $N$ users, the complexity of each iteration is $O(N^2M^2 + NM^3)$. By applying the convergence results of fixed-point algorithms [29], we obtain that the complexity of Algorithm 1 is $O((N^2M^2 + NM^3) \log c_1^{-1})$, where $c_1$ is a constant that determines the convergence speed of iterative operations in Algorithm 1. Following similar discussions, we obtain that the computational complexity of the large system iterative Algorithm 2 is $O(N^2 \log c_2^{-1})$, where $c_2$ is a constant that determines the convergence speed of iterative operations in Algorithm 2. If we use the exhaustive search method, the computational complexity will be $O(2N(N^2M^2 + NM^3)N_{\text{max}})$, where $N_{\text{max}}$ denotes the maximum number of iterations using the max-min SINR algorithm [28] to check the feasibility of the selected SAPs. Therefore, the proposed algorithms enjoy polynomial complexity with respect to $N$, which is much lower than the exponential complexity required by the exhaustive search method.

V. Simulation Results

A. Convergence Behavior of Finite System Iterative Algorithm

To verify the iterative algorithm for finite systems, we consider a heterogeneous cellular network, where the number of antennas at the WBH is $M = 3$ and the number of SAPs is $N = 4$. Each SAP has a single receive antenna for the wireless backhaul. The SINR requirement at each SAP for the wireless backhaul is set at $\gamma_i = 3.01 \text{dB}, \forall i = 1, \cdots, N$. The noise variance at each SAP is normalized to $n_i = 1 \text{Watt}, \forall i$. The transmit power constraint for wireless backhaul at the WBH is $P = 10 \text{Watt}$. In the whole simulations, the weights for the transmit power are set to $w_i = 1, \forall i$. A randomly generated channel is used to show the convergence result. We compare the results obtained by two methods: Algorithm 1 and alternate updates using cvx (AUC). In AUC, we solve (4) by alternatively solving (10) with fixed $\{u_i\}$ to obtain uplink power $q$ and updating the MMSE receiver $\{u_i^{\text{MMSE}}\}$ using the obtained $q$. In the end, we map the obtained uplink power $q$ into the corresponding downlink power $p$ that achieves the same SINR using uplink-downlink power mapping [30].

The convergence behavior of Algorithm 1 is shown in Fig. 2. Algorithm 1 converges to the same result obtained by AUC in less than 8 iterations. Fig. 2(a) shows the convergence results of $\{p_i\}$, and we initialize all $p_i$ with the same value. Fig. 2(b) shows the convergence results of $\{\nu_i\}$. After 8 iterations, the difference between Algorithm 1 and the final result of AUC is negligible.
Fig. 2. Convergence results for finite system iterative algorithms. The solid lines show the convergence of Algorithm 1 and the dashed lines show the final results obtained by AUC.

Fig. 3. Comparison of average simulation time for each channel realization using Algorithm 1 and AUC.

In order to compare the computational complexity of Algorithm 1 and AUC, we perform simulations on a PC with a Core 2 Duo CPU of internal clock 3.00GHz and 4GB RAM. Twenty channel realizations are performed for each algorithm. The number of SAPs varies from $N = 5$ to 20. The SINR requirements at the SAPs are set to $\gamma_i = 7.78$dB, $\forall i$. The stopping criteria for both algorithms are such that the maximum uplink power difference between neighboring iterations should be smaller than $\epsilon = 10^{-5}$. The average simulation time for each channel realization using Algorithm 1 and AUC is shown in Fig. 3. We observe that the average simulation time using AUC
is 5000 to 7000 times longer than that of Algorithm 1. Moreover, the ratio of simulation time increases with the number of SAPs $N$. This shows that the proposed iterative algorithm reduces huge amount of computation to solve (4) without invoking standard convex optimization software.

**B. Convergence Behavior of Large System Iterative Algorithm**

Numerical simulations are carried out to verify the iterative algorithm for large systems. In the simulation setup, the WBH has $M = 64$ antennas and there are $N = 32$ single antenna SAPs. The weights of power are set to $w_i = 1$, $\forall i$. The power constraint at the WBH is $P = 20$ Watt and the noise variance at each SAP is normalized to $n_i = 1$ Watt, $\forall i$. The SINR requirement at each SAP is set to $\gamma_i = 6.02$dB, $\forall i$. The large-scale fading coefficients $\{d_i\}$ between the WBH and the SAPs are assigned some randomly generated positive values, and they are fixed in the simulation.

In Fig. 4, we compare the results obtained by large system analysis with those obtained by Monte Carlo simulations. For the large system analysis, we calculate the transmit power $\{p_i/M\}$ and dual values of $\{\nu_i\}$ according to Algorithm 2. Those values are the theoretical deterministic quantities that $\{p_i/M\}$ and $\{\nu_i\}$ converge to when the system dimensions go to infinity, and they are shown in vertical bars for each SAP in Fig. 4(a) and Fig. 4(b), respectively. For the Monte Carlo simulations, 100 i.i.d. channel realizations are carried out. For each channel realization, the transmit power $\{p_i/M\}$ and dual values of $\{\nu_i\}$ are obtained using Algorithm 1. For each SAP $i$, the values of $p_i/M$ and $\nu_i$ obtained by Monte Carlo simulations are shown in error bars, where the mean value is indicated by a cross sign and the distance above and below the mean value denotes...
the standard deviation. We observe that the mean values accurately match the results obtained by large system analysis and the standard deviations are usually very small in both Fig. 4(a) and Fig. 4(b). This observation shows that \( \{p_i/M\} \) and \( \{\nu_i\} \) really converge to the deterministic quantities predicted by large system analysis irrespective of the actual channel realization as the system dimensions become large. Instead of the instantaneous channel information, the large system analysis Algorithm 2 utilizes the large-scale fading coefficients \( \{d_i\} \) as the channel inputs and requires infrequent updates.

C. SAP Admission Control

We perform numerical simulations for SAP admission control using a heterogeneous cellular network setup [31]. The WBH is located at the center of the cell. We assume the MBS is co-located with the WBH and has the same number of antennas. The cell radius is 1km. The transmit antenna gain at the WBH is 5dB. The pathloss model from the WBH to the SAPs is

\[
L(\text{dB}) = 128 + 37.6 \cdot \log_{10} D, \tag{48}
\]

where \( D \) represents the distance between the WBH and the SAP in the unit of km. The log-normal shadowing parameter is 10dB. The bandwidth of the wireless backhaul is 10MHz. The WBH transmit power constraint is 30dBm. The noise variance at each SAP is -93.98dBm. The cell radius of each small cell is 30m. We assume the SAPs are randomly and uniformly distributed within the cell. Table I shows a summary of the above simulation parameters.

In the numerical simulations for finite system SAP admission, we compare the proposed SAP admission control method, which employs Algorithm 1 and iterative SAP removal, to other two commonly used methods in literature: the Lagrange duality based heuristic removal user admission (HURA) algorithm [32] and the semiorthogonal user selection (SUS) algorithm [33]. We also compare the results with the exhaustive search (ES) method. The ES method obtains the maximum number of admitted SAPs by searching through all possible choices of SAPs and chooses the set of SAPs with the maximum cardinality. Even though the ES method produces the optimum results for (3), the computational load of the ES method is very high and it is only used as a benchmark for comparing different methods. We consider a network where the WBH has $M = 4$ antennas and there are $N = 12$ SAPs in the network. We generate 60 channel realizations for each SAP location layout and 20 different SAP location layouts are performed in simulations. The results for the considered methods are shown in Fig. 5. The average number of admitted SAPs for each channel realization is shown in Fig. 5(a). We observe that the average number of admitted SAPs by our proposed iterative method is nearly identical to that obtained by the optimum ES method. The HURA algorithm supports one less SAP compared to the ES method on average. The results achieved by the SUS algorithm is the worst, which is 2 to 1.2 less than the ES method. The transmit power $\sum_i p_i$ is shown in Fig. 5(b). Our proposed algorithm generally has higher power compared to HURA and SUS, but all the considered algorithms satisfy the transmit power constraint $P$.

We also perform simulations using the cellular network parameters in Table I for the case when the QoS requirements at different SAPs are unequal and change with time. In each time slot, the

SINR requirements at each SAP is drawn randomly from 4.3dB to 18.7dB. We compare the average simulation results for different SAP admission schemes in Table II. For the ES method, there may be more than one set of SAPs that have the maximum cardinality. In that case, we only randomly choose one set of SAPs from them due to complexity issues. For the unequal SINR requirements case, we observe from Table II that the average number of admitted SAPs for the proposed scheme is very close to the optimum results obtained by the ES method, which far outperforms the HURA and SUS methods. The average sum rate achieved by the proposed scheme is 60% and 73% higher than the HURA and SUS methods, respectively.

The simulation results comparing the user throughput with and without SAPs in a cellular network is shown in Table III. In the simulation, each SAP is responsible for serving one user. The SINR requirements of each user is drawn randomly from 4.3dB to 18.7dB. We use the simulation parameters in Table I and generate 60 different SAP location layouts. For each SAP location layout, 20 different user locations in each SAP are considered. We compare two cases: one is that the WBH performs SAP admission and transmit data to the admitted SAPs using wireless backhaul, and then the admitted SAPs transmit those data to their users using in-band channel taking into account the intercell interference; the other is that the users are served directly by the MBS using in-band channel. In both cases, the transmit power of in-band channel is the same. In Table III, we observe that the user throughput with SAP admission is about 10 times that without SAPs. This is because the deployment of SAPs significantly reduces the distance between the transmitters and users. Without using small cells, the signal strength at the users will be much weaker when transmitted from the MBS. This shows that small cells can boost the system throughput considerably.

The simulations for large systems are carried out employing cellular network parameters of Table I. In the simulations, the WBH is equipped with $M = 64$ antennas and there are $N = 32$ single antenna SAPs. The weights of power are set to $w_i = 1$, $\forall i$. The power constraints are set to $P = 30$dBm, 27.0dBm, and 24.8dBm. We compare the simulation results using large system analysis and those using Monte Carlo simulations in Fig. 6. Fig. 6(a) compares the number of admitted SAPs under given power and SINR constraints. The asymptotic results are shown in

circles, and they are obtained by the SAP admission control method employing Algorithm 2 and iterative SAP removal using large-scale fading coefficients. Those asymptotic results are compared to the Monte Carlo simulation results, where 100 i.i.d. channel realizations are carried out. For each channel realization, the Monte Carlo simulation performs SAP admission employing Algorithm 1 and iterative SAP removal. Those Monte Carlo results are shown in error bars. We observe from Fig. 6(a) that the standard deviations of the Monte Carlo results are very small, which shows the Monte Carlo results tend to be deterministic values. Such deterministic values are accurately predicted by the asymptotic results using large system analysis. In Fig. 6(b), we show the achieved minimum SINR by the SAPs that are selected employing the large system analysis. For the given SINR constraint and large-scale fading coefficients, the set of admitted SAPs is selected using the SAP admission control method employing Algorithm 2 and iterative SAP removal. The max-min SINR algorithm [28] is utilized for each channel realization to maximize the minimum SINR for that set of admitted SAPs over 100 i.i.d. channel realizations. The error bars show the achieved SINR
values for different channel realizations, which are very close or above the SINR requirements. Fig. 6(b) shows that the admitted SAPs can satisfy the SINR requirements in nearly all channel realizations even though the SAPs are selected using large system analysis.

VI. CONCLUSION

We considered the problem of SAP admission control in a heterogeneous cellular network using wireless backhaul. In order to divert the data traffic from the macrocell to small cells, as well as to minimize the total cost of building backhaul to serve small cells in the network, the WBH needs to simultaneously serve as many SAPs as possible under given power and SINR constraints. Such a problem is combinatorial and NP-hard. We applied \( \ell_1 \)-norm relaxation and proposed an iterative algorithm to solve the relaxed problem. The local convergence property of the iterative algorithm was proved. Based on the solution of the \( \ell_1 \)-relaxed problem, the SAPs were iteratively removed until all the remaining SAPs can satisfy the power and SINR constraints. We also proposed a large system iterative algorithm using random matrix theory. Such an algorithm only requires large-scale channel coefficients to perform SAP admission control for large systems irrespective of instantaneous channel information. Simulations showed that the finite system iterative algorithm achieved near optimum results and the large system iterative algorithm predicted the Monte Carlo simulation results accurately.

APPENDIX A

PROOF OF LEMMA 1

For any set of given beamformers \( \{u_i\} \), according to [34, Proposition 27.2], both the uplink and downlink have the same SINR feasible region under the power constraint \( P \) with the uplink and downlink SINR definition of (6) and (2), respectively. The target SINRs \( \gamma_i/(1 + x_i) \), \( \forall i \), are feasible in the downlink if and only if the same targets are feasible in the uplink. Therefore, the same set of \( x \) is feasible for (4) and (5) under the power constraint \( P \). Since this is true for any set of beamformers \( \{u_i\} \), the optimum solution of \( \{u_i\} \) and \( x \) in (4) and (5) are the same. For given \( \{u_i\} \) and \( x \), the mapping between uplink power \( q \) and downlink power \( p \) that achieves the same SINRs can be obtained by the uplink-downlink power mapping [27].

APPENDIX B

PROOF OF LEMMA 2

Consider the uplink power allocation \( q^* \), it is known [35] that the uplink SINR (6) is maximized by the MMSE receiver, i.e., \( \text{SINR}^U_{i} (q^*, \{u^\text{MMSE}_i\}) \geq \text{SINR}^U_{i} (q^*, \{u_i\}) \). If \( u_i \neq u^\text{MMSE}_i \) in the solution of (5), substituting \( u_i \) with \( u^\text{MMSE}_i \) will also satisfy (5). Therefore, \( \{u^\text{MMSE}_i\} \) must be the
solution of optimum receive beamformers in (5). The corresponding SINR can be obtained by substituting (7) into (6).

APPENDIX C
PROOF OF THEOREM

The Lagrangian of (10) can be expressed as

$$
\mathcal{L}(\tilde{q}, \{u_i\}, x) = \sum_i (1-\alpha_i)x_i + \sum_i \nu_i \left( \log \frac{\gamma_i \left( \sum_{j \neq i} G_{ji} e^{\tilde{q}_j} + w_i \right)}{G_{ii} e^{\tilde{q}_i}} - \log(1 + x_i) \right) + \mu \left( \sum_i n_i e^{\tilde{q}_i} - P \right).
$$  \hspace{1cm} (49)

According to the KKT conditions, we have

$$
\frac{\partial \mathcal{L}}{\partial x_i} = 1 - \alpha_i - \frac{\nu_i}{1 + x_i} = 0, \quad \forall i = 1, \cdots, N; \hspace{1cm} (50)
$$

$$
\frac{\partial \mathcal{L}}{\partial \tilde{q}_i} = -\nu_i + \sum_{j \neq i} \nu_j \frac{G_{ij} e^{\tilde{q}_i}}{\sum_{k \neq j} G_{kj} e^{\tilde{q}_k} + w_j} + \mu n_i e^{\tilde{q}_i} = 0, \quad \forall i. \hspace{1cm} (51)
$$

Therefore, we have

$$
x_i = \max (\nu_i - 1, 0), \quad \forall i; \hspace{1cm} (52)
$$

$$
\nu_i = \left( \sum_{j \neq i} \frac{\nu_j G_{ij}}{\sum_{k \neq j} G_{kj} e^{\tilde{q}_k} + w_j} + \mu n_i \right) e^{\tilde{q}_i}, \quad \forall i. \hspace{1cm} (53)
$$

Because $e^{\tilde{q}_i} > 0$, any $\nu_i = 0$ requires $\mu = 0$ and $\nu_j = 0, \forall j = 1, \cdots, N$, simultaneously. By abandoning this trivial solution, we have $\mu > 0$ and $\nu_i > 0, \forall i$. According to the complementary slackness conditions [36] and substituting $e^{\tilde{q}_i} = q_i/M$, we have

$$
\frac{(1 + x_i) G_{ii} q_i}{M \gamma_i} = \sum_{j \neq i} \frac{G_{ij} q_i}{M} + w_i, \quad \forall i; \hspace{1cm} (54)
$$

$$
\sum_i \frac{n_i q_i}{M} = P. \hspace{1cm} (55)
$$

Substituting (54) into (53), we have

$$
\frac{M \nu_i}{q_i} = \sum_{j \neq i} \frac{M G_{ij} \gamma_j \nu_j}{(1 + x_j) G_{jj} q_j} + \mu n_i, \quad \forall i. \hspace{1cm} (56)
$$

Therefore

$$
\frac{(1 + x_i) G_{ii} \nu_i}{\gamma_i} = \frac{M \gamma_i \nu_i}{(1 + x_i) G_{ii} q_i \mu} = \sum_{j \neq i} \frac{G_{ij} \gamma_j \nu_j}{(1 + x_j) G_{jj} q_j \mu} + n_i, \quad \forall i. \hspace{1cm} (57)
$$

We define

$$
\frac{p_i}{M} \triangleq \frac{M \gamma_i \nu_i}{(1 + x_i) G_{ii} q_i \mu}, \quad \forall i \hspace{1cm} (58)
$$
and we have
\[(1 + x_i) G_{ii} p_i = \sum_{j \neq i} G_{ij} p_j M^\gamma_i + n_i, \quad \forall i. \tag{59}\]

Multiply both sides of (54) with \(p_i\) and sum them up for all \(i\). We also multiply both sides of (59) with \(q_i\) and sum them up for all \(i\). Because \(\sum_i \sum_{j \neq i} G_{ij} q_j p_i = \sum_i \sum_{j \neq i} G_{ij} q_i p_j\), we have
\[
\sum_i w_i p_i M^\gamma_i = \sum_i n_i q_i M^\gamma_i = P. \tag{60}\]

Eq. (59) shows the power allocation \(p\) defined in (58) achieves the same SINR as the uplink \(q\). Eq. (60) shows \(p\) satisfies the same power constraint as \(q\). When the variables on the right-hand-side of (58) are the optimum primal and dual solutions of (5), the power \(p\) defined in (58) corresponds to the optimum downlink power that solves (4) according to Lemma 1.

**APPENDIX D**

**PROOF OF THEOREM 2**

We only show the proof assuming that \(\nu^*_i \geq 1, \forall i\), at the optimum solution of (5). The proof that some \(\nu^*_i < 1\) can be obtained likewise. Since we consider points that are sufficiently close to the optimum solution, we assume the beamformers \(\{u_i\}\) to be sufficiently close to the optimum beamformers \(\{u^*_i\}\). Then the equivalent channel is \(G_{ij} = |h_i^H u^*_j|^2, \forall i, j\), and it can be assumed to be fixed. The updates in Algorithm 1 boil down to the updates of \(q_i\) and \(\nu_i\), \(\forall i\). We define a vector \(\omega \in \mathbb{R}^N_+\) and a matrix \(F \in \mathbb{R}^{N \times N}_+\), where
\[
\omega_i = M w_i \gamma_i / G_{ii}, \forall i = 1, \cdots, N, \text{ and } \quad F_{ij} = \begin{cases} G_{ij} / G_{ii}, & \text{if } i \neq j; \\ 0, & \text{if } i = j. \end{cases} \tag{61}\]

Furthermore, we introduce a vector \(y = [y_1, \cdots, y_N]^T\), where \(y_i = \nu_i / q_i, \forall i\). Therefore, \(\nu = y \circ q\).

The updates of \(q\) in (23) is actually obtained from the KKT condition (13) using MMSE receivers \(\{u_i\}\). Since we assume \(\nu^* \geq 1\) and \(u_i \approx u^*_i\) here, the updates of \(q\) can be expressed as
\[
q^{(m+1)} = \text{diag} \left( \nu^{(m)} \right)^{-1} \left( F^T q^{(m)} + \omega \right) \tag{62}
\]
\[
= \text{diag} \left( q^{(m)} \circ y^{(m)} \right)^{-1} \left( F^T q^{(m)} + \omega \right). \tag{63}
\]

By substituting (28) and (29) into (30), the updates of \(y\), which is obtained by \(y = \nu \circ q^{-1}\), can be expressed as
\[
y^{(m+1)} = F \cdot (q^{(m)})^{-1} + \frac{1}{MP} n \cdot \left( \omega^T (q^{(m)})^{-1} \right) \tag{64}
\]
\[
= \left( F + \frac{1}{MP} n \omega^T \right) (q^{(m)})^{-1}. \tag{65}
\]
By dropping the time indices and letting $z = [q^T, y^T]^T$, the fixed-point updates of $z$ can be expressed as

$$T(z) = \begin{pmatrix} f_1(q, y) \\ f_2(q, y) \end{pmatrix} = \begin{pmatrix} \text{diag}(q \circ y)^{-1}(F^T q + \omega) \\ F + \frac{1}{MP} n\omega^T \end{pmatrix} q^{-1}. \quad (66)$$

Its Jacobian matrix can be written as

$$J = \begin{pmatrix} \partial f_1 / \partial q^T & \partial f_1 / \partial y^T \\ \partial f_2 / \partial q^T & \partial f_2 / \partial y^T \end{pmatrix} = \begin{pmatrix} \text{diag}(q \circ y)^{-1} F^T & 0 \\ 0 & 0 \end{pmatrix} - E : \begin{pmatrix} \text{diag}(q \circ y)^{-2} & 0 \\ 0 & \text{diag}(q \circ y)^{-2} \end{pmatrix} \quad (68)$$

where

$$E = \begin{pmatrix} \text{diag}(F^T q + \omega) \text{diag}(y) & \text{diag}(F^T q + \omega) \text{diag}(q) \\ (F + \frac{1}{MP} n\omega^T) \text{diag}(y)^2 & 0 \end{pmatrix}. \quad (69)$$

At the optimum solution, we have

$$q^* = \text{diag}(q^* \circ y^*)^{-1}(F^T q + \omega) \quad (70)$$
$$y^* = \left( F + \frac{1}{MP} n\omega^T \right) (q^*)^{-1}. \quad (71)$$

Substitute (70) back to (69). Let $J^* = J(q = q^*, y = y^*)$ and $A = J^* + I$, we have

$$A = \begin{pmatrix} \text{diag}(q^* \circ y^*)^{-1} F^T & \text{diag}(q^*) \text{diag}(y^*)^{-1} \\ (F + \frac{1}{MP} n\omega^T) \text{diag}(q^*)^{-2} & I \end{pmatrix}. \quad (72)$$

The matrix $A$ is nonnegative and irreducible. Furthermore, we have

$$A \cdot \begin{pmatrix} q^* \\ y^* \end{pmatrix} + \begin{pmatrix} \text{diag}(q^* \circ y)^{-1} \omega \\ 0 \end{pmatrix} = 2 \begin{pmatrix} q^* \\ y^* \end{pmatrix} \quad (73)$$

according to (70) and (71). Therefore,

$$A \cdot \begin{pmatrix} q^* \\ y^* \end{pmatrix} \preceq 2 \begin{pmatrix} q^* \\ y^* \end{pmatrix} \quad (74)$$

and $[(q^*)^T, (y^*)^T]^T \succeq 0$. Because $A$ is nonnegative and irreducible, (74) implies its spectral radius $\rho(A) < 2$ according to [37, Theorem 1.11].

To ensure contraction mapping of the algorithm, the step (25) must be invoked. Consider the update

$$z^{(m+1)} = \frac{1}{2} z^{(m)} + \frac{1}{2} T(z^{(m)}). \quad (75)$$
Let $z^{(m)} = z^* - \varepsilon^{(m)}$ and $z^{(m+1)} = z^* - \varepsilon^{(m+1)}$, where $z^*$ is the optimum solution. Then

\begin{align}
  z^* - \varepsilon^{(m+1)} &= \frac{1}{2}(z^* - \varepsilon^{(m)}) + \frac{1}{2}T(z^* - \varepsilon^{(m)}) \\
  &\approx \frac{1}{2}(z^* - \varepsilon^{(m)}) + \frac{1}{2}(T(z^*) - J^* \cdot \varepsilon^{(m)}) \\
  &= z^* - \left(\frac{1}{2}I + \frac{1}{2}J^*\right)\varepsilon^{(m)}. \tag{76}
\end{align}

Here we used $z^* = T(z^*)$. Therefore,

\[ \varepsilon^{(m+1)} \approx \left(\frac{1}{2}I + \frac{1}{2}J^*\right)\varepsilon^{(m)}. \tag{79} \]

Because $\rho(A) < 2$, we have $\rho(\frac{1}{2}I + \frac{1}{2}J^*) < 1$. This shows there exists neighborhood of the optimum solution, which ensures the mapping in Algorithm 1 to be a contraction mapping that satisfies the Lipschitz condition \[38\]. Therefore, Algorithm 1 converges to the optimum solution if the starting point is within this neighborhood.

**APPENDIX E**

**USEFUL RESULTS FROM RANDOM MATRIX THEORY**

We summarize some useful results obtained from random matrix theory.

**Lemma 6:** (Trace lemma \[39\], \[40\]) Let $A \in \mathbb{C}^{M \times M}$ and $x \in \mathbb{C}^M$ be a random vector of i.i.d. entries, independent of $A$. Assume $E(x_i) = 0$, $E(|x|^2) = 1$, $E(|x|^8) < \infty$, and $\limsup_M \|A\| < \infty$. Then

\[ \frac{1}{M}x^HAx - \frac{1}{M} \text{tr}(A) \xrightarrow{a.s.} 0. \tag{80} \]

**Lemma 7:** (Rank-1 perturbation lemma \[41\]) Let $z < 0$, $A \in \mathbb{C}^{M \times M}$ and $B \in \mathbb{C}^{M \times M}$, with $B$ Hermitian nonnegative definite, and $x \in \mathbb{C}^M$. Assume $\limsup_M \|A\| < \infty$. Then

\[ \left| \frac{1}{M} \text{tr} \left( (B - zI)^{-1} - (B + xx^H - zI)^{-1} \right) A \right| \leq \frac{\|A\|}{M|z|} \to 0, \quad \text{as } M \to \infty. \tag{81} \]

This shows that finite rank perturbations of $B$ are asymptotically negligible.

**Lemma 8:** (Right-sided correlation model \[42\], \[43\]) Let $X \in \mathbb{C}^{M \times K}$, $[X]_{i,j} \sim \mathcal{CN}(0, \frac{1}{K})$ i.i.d., and let $T = \text{diag}(t_1, \cdots, t_K) \in \mathbb{R}_{+}^{K \times K}$ be deterministic, satisfying $\max_k t_k < \infty$. Denote $B = XTX^H$, $c = M/K$, and let $M, K \to \infty$ while $0 < \liminf c \leq \limsup c < \infty$. Then

\[ \frac{1}{M} \text{tr} \left( (B - zI)^{-1} - \psi(z) \right) \xrightarrow{a.s.} 0, \quad \text{for } z < 0 \tag{82} \]

where $\psi(z)$ is the unique Stieltjes transform \[44\] which satisfies

\[ \psi(z) = \left( \frac{1}{K} \sum_{k=1}^{K} \frac{t_k}{1 + ct_k \psi(z) - z} \right)^{-1}. \tag{83} \]
Lemma 9: (Matrix inversion lemma [42]) Let $A \in \mathbb{C}^{M \times M}$ be invertible. Then for any vector $x \in \mathbb{C}^M$ and any scalar $c \in \mathbb{C}$ such that $A + cxx^H$ is invertible,

$$x^H (A + cxx^H)^{-1} = \frac{x^H A^{-1}}{1 + cxx^H A^{-1}x}.$$  \hspace{1cm} (84)

### Appendix F

**Proof of Lemma 3**

According to Lemma 6 we have

$$\frac{1}{M} \tilde{h}_i^H \left( \sum_{j \neq i} \frac{q_j d_j}{M} \tilde{h}_j \tilde{h}_j^H + w_i I \right)^{-1} \tilde{h}_i - \frac{1}{M} \text{tr} \left( \sum_{j \neq i} \frac{q_j d_j}{M} \tilde{h}_j \tilde{h}_j^H + w_i I \right)^{-1} \xrightarrow{\text{a.s.}} 0. \hspace{1cm} (85)$$

Furthermore, by applying Lemma 8 and substituting $z = -w_i$, $t_j = \frac{q_j d_j K}{M}$, $\forall j \neq i$, we have

$$\frac{1}{M} \text{tr} \left( \sum_{j \neq i} \frac{q_j d_j}{M} \tilde{h}_j \tilde{h}_j^H + w_i I \right)^{-1} - \varphi_i(q) \xrightarrow{\text{a.s.}} 0, \hspace{1cm} (86)$$

where

$$\varphi_i(q) = \left( w_i + \frac{1}{M} \sum_{j \neq i} \frac{q_j d_j}{1 + q_j d_j \varphi_i(q)} \right)^{-1}, \hspace{1cm} \forall i = 1, \cdots, N. \hspace{1cm} (87)$$

Therefore, we have \( \text{SINR}_i(q, \{u_i^{\text{MMSE}}\}) \xrightarrow{\text{a.s.}} q_i d_i \varphi_i(q). \)

### Appendix G

**Proof of Lemma 4**

Substituting the expression of $u_i^{\text{MMSE}}$ (7) into (36), we have

$$\frac{1}{M} \left| \tilde{h}_i^H u_i^{\text{MMSE}} \right|^2 = \frac{\left( \frac{1}{M} \tilde{h}_i \left( \sum_{j \neq i} \frac{q_j d_j}{M} \tilde{h}_j \tilde{h}_j^H + w_i I \right)^{-1} \tilde{h}_i^H \right)^2}{\frac{1}{M} \tilde{h}_i \left( \sum_{j \neq i} \frac{q_j d_j}{M} \tilde{h}_j \tilde{h}_j^H + w_i I \right)^{-2} \tilde{h}_i^H}. \hspace{1cm} (88)$$

According to Lemma 3, the numerator of (88) converges almost surely to $\varphi_i^2(q)$.

The deterministic equivalent for the denominator can be obtained from Lemma 8. Under the assumptions of Lemma 8 and taking derivative of the Stieltjes transform in (82), we have

$$\frac{1}{M} \text{tr} (B - zI)^{-2} \xrightarrow{\text{a.s.}} -\psi'(z), \hspace{1cm} \text{for } z < 0 \hspace{1cm} (89)$$

where

$$\psi'(z) = \frac{d\psi(z)}{dz}. \hspace{1cm} (90)$$
By making use of the rules for implicit differentiation [45], the value of $\psi'(z)$ can be expressed as

$$\psi'(z) = -\psi(z) \cdot \left( \frac{1}{K} \sum_{k=1}^{K} \frac{t_k}{(1 + ct_k \psi(z))^2} - z \right)^{-1}.$$  \hspace{1cm} (91)

By substituting $z = -w_i, t_j = \frac{q_j d_j K}{M}, \forall j \neq i$ into (91), we have

$$\frac{1}{M} \tilde{h}_i \left( \sum_{j \neq i} q_j d_j \tilde{h}_j^H + w_i I \right)^{-2} \tilde{h}_i^H \overset{a.s.}{\rightarrow} -\varphi'_i(q)$$  \hspace{1cm} (92)

where $\varphi'_i(q) = -\varphi_i(q) \cdot \left( w_i + \frac{1}{M} \sum_{j \neq i} \frac{q_j d_j}{(1 + q_j d_j \psi(q))^2} \right)^{-1}$.

**APPENDIX H**

**PROOF OF LEMMA 5**

The expression of $\left| \tilde{h}_i^H u_j^\text{MMSE} \right|^2$ can be further expended as

$$\left| \tilde{h}_i^H u_j^\text{MMSE} \right|^2 = \frac{1}{M} \tilde{h}_j \left( \sum_{k \neq j,i} \frac{q_k d_k}{M} \tilde{h}_k \tilde{h}_k^H + w_j I \right)^{-1} \tilde{h}_i \tilde{h}_i^H \left( \sum_{k \neq j,i} \frac{q_k d_k}{M} \tilde{h}_k \tilde{h}_k^H + w_j I \right)^{-1} \tilde{h}_j.$$  \hspace{1cm} (93)

The denominator of (93) converges almost surely to $-\varphi'_j(q)$ according to the proof of Lemma 4. For the numerator of (93), since $\tilde{h}_i$ and $\sum_{k \neq j,i} \frac{q_k d_k}{M} \tilde{h}_k \tilde{h}_k^H$ are not independent, the numerator is transformed into the following equivalent form using matrix inversion lemma

$$\frac{1}{M} \tilde{h}_j \left( \sum_{k \neq j,i} \frac{q_k d_k}{M} \tilde{h}_k \tilde{h}_k^H + w_j I \right)^{-1} \tilde{h}_i \tilde{h}_i^H \left( \sum_{k \neq j,i} \frac{q_k d_k}{M} \tilde{h}_k \tilde{h}_k^H + w_j I \right)^{-1} \tilde{h}_j \left( 1 + \frac{q_i d_i}{M} \tilde{h}_i \left( \sum_{k \neq j,i} \frac{q_k d_k}{M} \tilde{h}_k \tilde{h}_k^H + w_j I \right)^{-1} \tilde{h}_i \right)^2.$$  \hspace{1cm} (94)

According to the proof of Lemma 4 and employing rank-1 perturbation lemma, the numerator of (94) converges almost surely to $-\varphi'_j(q)$ and the denominator of (94) converges almost surely to $(1 + q_i d_i \varphi_j(q))^2$.

**ACKNOWLEDGMENT**

The authors would like to thank Prof. Chee Wei Tan and Mr. Xianping Zhai for helpful discussions.
