Abstract
This paper focuses on computing general first-order parallel and prioritized circumscription with varying constants. We propose linear translations from general first-order circumscription to first-order theories under stable model semantics over arbitrary structures, including $Tr_s$ for parallel circumscription and $Tr^*_s$ for conjunction of parallel circumscriptions (further for prioritized circumscription). To improve the efficiency, we give an optimization $\Gamma_3$ to reduce logic programs in size when eliminating existential quantifiers during the translations. Based on these results, a general first-order circumscription solver, named cfo2lp, is developed by calling answer set programming (ASP) solvers. Using circuit diagnosis problem and extended stable marriage problem as benchmarks, we compare cfo2lp with a propositional circumscription solver circ2dlp and an ASP solver with complex optimization metasp on efficiency. Experimental results demonstrate that for problems represented by first-order circumscription naturally and intuitively, cfo2lp can compute all solutions over finite structures. We also apply our approach to description logics with circumscription and repairs in inconsistent databases, which can be handled effectively.

Introduction
As an elegant formalism for modelling non-monotonic reasoning, circumscription was introduced by McCarthy to formalize common sense reasoning in (McCarthy 1980; 1986). Lifschitz (1994) presented precise definitions of general first-order (FO) parallel and prioritized circumscription with varying constants, rewritten as a second-order (SO) sentence. Circumscription is theoretically significant because of not only its elegant syntax and semantics, but its expressive power to capture more exact inclusions naturally.

However, circumscription has encountered difficulties from a practical viewpoint. So far researchers have developed methods to compute circumscription, however, the computation still remains unsatisfactory. Lifschitz (1994) discussed computational methods for simplifying FO circumscription. Cadoli, Eiter, and Gottlob (1992) eliminated varying predicates in inference, deciding whether a given formula is entailed by a parallel circumscription. Doherty, Łukaszewicz, and Szalas (1997) reduced limited circumscription to FO formulas. Wakaki and Inoue (2004) compiled FO prioritized circumscription without existential quantifiers into logic programs. Oikarinen and Janhunen (2005; 2008) presented a linear transformation to convert prioritized circumscription to logic programs and developed a propositional solver circ2dlp. Lee and Palla (2009; 2012) and Kim, Lee, and Palla (2009) presented a translation to compute a certain class of FO circumscription (named “canonical”). Zhang et al. (2011) embedded FO circumscription without varying constants into theories under stable model semantics. Gebser, Kaminski, and Schaub (2011) developed an implementation of finding inclusion-based minimal answer sets. Up to now, we have not found a solver for computing all models satisfying general FO parallel and prioritized circumscription with varying constants.

The aim of this paper is to achieve a practically usable computational approach and to apply its implementation. First, we propose and prove linear translations from general FO circumscription with varying constants to FO theories under stable model semantics over arbitrary structures: (i) $Tr_s$ for parallel circumscription, (ii) $Tr^*_s$ for conjunction of parallel circumscriptions and further for prioritized circumscription. Secondly, based on these reductions, we can compute general FO circumscription by using existing answer set programming (ASP) solvers, over finite structures. To improve the efficiency, an optimization $\Gamma_3$ is given to downsizes logic programs when eliminating existential quantifiers during the translations. Thirdly, we develop a solver, named cfo2lp. To compare it with circ2dlp and metasp on efficiency, we use circuit diagnosis problem and extended stable marriage problem as benchmarks. Experimental results demonstrate that our approach can effectively solve problems represented naturally by FO circumscription and find all the solutions. Finally, we apply our approach to description logics (DLs) with circumscription and minimal repairs in inconsistent databases, which can be handled effectively.

Preliminaries
The notions of FO language are defined as usual. A FO formula is in prenex normal form (PNF) if it is of the form $Q_1x_1, \ldots, Q_nx_n\varphi$ where $Q_i(i = 1, \ldots, n)$ is $\exists$ or $\forall$ and $\varphi$ is quantifier-free. A FO formula is in negation normal form...
Circumscription

We follow the notions of parallel and prioritized circumscription in (Lifschitz 1994). A general FO circumscription is viewed as a FO sentence in circumscription. Let \( \varphi \) be a FO sentence; its vocabulary is divided into three mutually disjoint tuples: minimized predicate constants \( \sigma_m \), varying constants \( \sigma_v \), and fixed constants. For each \( P \in \sigma_m \), a predicate variable \( P^* \) with the same arity is introduced and let \( \sigma_m \) be the tuple of such \( P^* \). Similarly, the tuple \( \sigma_v^* \) of individual, function, and predicate variables is introduced for \( \sigma_v \).

Next, we introduce a comparison relation \( < \) between two predicate tuples. Moreover, we use \( \sigma^*_m = \sigma_m (\text{resp. } \sigma^*_m \leq \sigma_m) \) as a shorthand for the conjunction of \( \forall \bar{x}(P^*(\bar{x}) \leftrightarrow P(\bar{x})) \) (resp. \( \forall \bar{x}(P^*(\bar{x}) \rightarrow P(\bar{x})) \)) for all \( P^* \in \sigma^*_m \) and \( P \in \sigma_m \). And let the comparison \( \sigma^*_m < \sigma_m \) denote the formula \( (\sigma^*_m \leq \sigma_m) \land \neg(\sigma^*_m = \sigma_m) \). Then parallel circumscription of \( \sigma_m \) for \( \varphi \) with \( \sigma_v \) varying is denoted by a SO formula:

\[
\text{CIRC}[\varphi; \sigma_m; \sigma_v] = \varphi \land \forall \sigma^*_m \exists \sigma_v^*(\sigma^*_m < \sigma_m \rightarrow \neg \varphi(\sigma^*_m, \sigma_v^*))
\]

where \( \varphi(\sigma^*_m, \sigma_v^*) \) is obtained by substituting variables in \( \sigma^*_m \) (resp. \( \sigma_v^* \)) for corresponding constants in \( \sigma_m \) (resp. \( \sigma_v \)).

Intuitively, circumscription makes the interpretation of predicates in \( \sigma_m \) minimal under the precondition guaranteeing the validity of \( \varphi \). A structure \( \mathfrak{A} \) is a \( \sigma_m \)-minimal model of \( \varphi \) with \( \sigma_v \) varying if it is a model of \( \text{CIRC}[\varphi; \sigma_m; \sigma_v] \).

If \( \sigma_m \) is decomposed into \( k \) disjoint parts \( \sigma_1, \ldots, \sigma_k \), and members of \( \sigma_i \) are assigned a higher priority than those of \( \sigma_j \) for \( 1 \leq i < j \leq k \), then prioritized circumscription of such order for \( \varphi \) with \( \sigma_v \) varying is denoted by \( \text{CIRC}[\varphi; \sigma_1 > \ldots > \sigma_k; \sigma_v] \), also defined by a SO formula. That is, predicates of higher priority are more important than those of lower priority and the former should be minimized further.

**Example 1** [Reiter’s Example, [McCarthy,1986] Section 7]

\[
\text{Quaker}(x) \land \neg \text{Ab}_1(x) \rightarrow \text{Pacifist}(x)
\]

\[
\text{Republican}(x) \land \neg \text{Ab}_2(x) \rightarrow \neg \text{Pacifist}(x)
\]

If \( \text{Nixon} \) is both a \( \text{Quaker} \) and a \( \text{Republican} \), there is no conclusion on whether he is a \( \text{Pacifist} \) or not, even circumscribing \( \text{Ab}_1 \) and \( \text{Ab}_2 \) in \( \varphi \). However if it is considered that \( \text{Nixon} \) is more likely to be a normal \( \text{Quaker} \) than a normal \( \text{Republican} \), we can conclude that \( \text{Nixon} \) is a \( \text{Pacifist} \) by computing \( \text{CIRC}(2) \land (3); \text{Ab}_1 > \text{Ab}_2; \text{Pacifist} \).

Stable Model Semantics

Similar to circumscription, a FO theory under stable model semantics (SM-semantics) was generalized in (Ferraris, Lee, and Lifschitz 2007; Lin and Zhou 2011). For a FO sentence \( \psi \) and a tuple \( \sigma_i \) of predicate constants, define SM\([\psi; \sigma_i]\) as:

\[
\text{SM}[\psi; \sigma_i] = \psi \land \forall \sigma_i^*(\sigma_i^* < \sigma_i \rightarrow \neg \text{St}(\psi; \sigma_i))
\]

where \( \text{St}(\psi; \sigma_i) \) is defined recursively as follows:

- \( \text{St}(P(\bar{x}); \sigma_i) = P^*(\bar{x}) \) if \( P \in \sigma_i \);
- \( \text{St}(F(\bar{x}); \sigma_i) = F(\bar{x}) \) if \( F \) is a predicate not in \( \sigma_i \);
- \( \text{St}(\psi_1 \circ \psi_2; \sigma_i) = \text{St}(\psi_1; \sigma_i) \circ \text{St}(\psi_2; \sigma_i) \) if \( \circ \in \{\land, \lor\} \);
- \( \text{St}(\psi_1 \rightarrow \psi_2; \sigma_i) = (\text{St}(\psi_1; \sigma_i) \rightarrow \text{St}(\psi_2; \sigma_i)) \land (\psi_1 \rightarrow \psi_2) \);
- \( \text{St}(Qx\psi_1; \sigma_i) = Qx\text{St}(\psi_1; \sigma_i) \) if \( Q \in \{\forall, \exists\} \).

A structure \( \mathfrak{A} \) is called a \( \sigma_i \)-stable model of \( \varphi \) if it is a model of \( \text{SM}[\varphi; \sigma_i] \). A (predicate) constant is intensional if it occurs in \( \sigma_i \); otherwise, it is extensional.

From Circumscription to SM-semantics

Note that the equivalence between formulas in classical FO logic is still retained in circumscription. So for every FO formula, there always exists a formula in NNF equivalent to it in circumscription. NNF guarantees that \( \top \) only occurs directly ahead of predicates. Here \( \neg P \) is treated as \( P \rightarrow \bot \), called negative literal conveniently. The implications always follow predicates, so that they are handled easily when taking into account the operator St. Thus the translations in this section take formulas in NNF as inputs.

Parallel Circumscription

Now we pay attention to parallel circumscription with varying predicate constants, a specialization of prioritized circumscription. As formulas (1) and (4) show, parallel circumscription and theories under SM-semantics are similar in mathematical definition, denoted by a SO formula. It is necessary to introduce auxiliary predicates for translations from (1) to (4). There are four challenges in finding a translation:

1. Keep the equivalence between the original sentence \( \varphi \) and the resulting sentence \( \psi \) under FO classical logic;
2. Simulate the varying predicate constants \( \sigma_v \) whose corresponding variables \( \sigma_v^* \) can change arbitrarily;
3. Forbid auxiliary predicates from affecting the minimized predicates comparison \( \sigma^*_m < \sigma_m \);
4. Make the resulting formula \( \text{St}(\psi; \sigma_i) \) equivalent to the original one \( \varphi(\sigma^*_m, \sigma_v^*) \).

Fortunately, we find such a linear translation:

**Definition 1** Let \( \varphi \) be any FO sentence in NNF. Let \( \sigma_m \) and \( \sigma_v \) be two disjoint tuples of predicates respectively. Then define \( \text{Tr}_v(\varphi; \sigma_m; \sigma_v) \) as the conjunction of the following:

\[
\varphi^{\sim_m} \land \bar{\varphi}
\]

\[
\gamma \leftrightarrow \bigwedge_{P \in \sigma_m} \forall \bar{x}(P(\bar{x}) \lor \neg P(\bar{x}))
\]

\[
\bigwedge_{Q \in \sigma_v} \forall \bar{x}(\gamma \rightarrow Q'(\bar{x}))
\]

where \( \varphi^{\sim_m} \) is obtained from \( \varphi \) by substituting \( \neg P(\bar{x}) \) for each positive literal \( P(\bar{x}) \) s.t. \( P \in \sigma_m \); \( \bar{\varphi} \) is obtained from \( \varphi \) by substituting \( \neg P(\bar{x}) \) for each negative literal \( \neg P(\bar{x}) \) s.t. \( P \in \sigma_m \); and \( Q' \) is the corresponding auxiliary predicate not in \( \varphi \) of the same arity for every \( Q \) and \( \sigma_v^* \) is the tuple of \( \sigma_v \).

Intuitively, translation \( \text{Tr}_v \) at first guarantees the resulting sentence is equivalent to the original one in FO classical logic. According to the definition of operator St, when
σ^*_m < σ_m, γ is true while St(γ) \^ is false and when σ^*_m = σ_m, both are true. Thus, St(P(\bar{x}) → γ) is equivalent to \neg P^*(\bar{x}).

Formula (7) plays a key role in Tr_v. St((7)) leads to the arbitrariness assignment of predicate variable Q^* and guarantees Q^* \leq Q'. What’s more, the minimized predicates comparison relation σ^*_m < σ_m is equivalent to that of intensional predicates. Then ϕ^~m remains equivalent to St(ϕ^~m) and St(ϕ) simulates ϕ(σ^*_m, σ^* v) in circumscription.

**Proposition 1** Let ϕ be any FO sentence in NNF. Let σ_m and σ_v be two disjoint tuples of predicate constants. Then \exists[σ^*_m] \exists[σ^* v]SM[Tr_v(ϕ; σ_m; σ_v)] 2 is equivalent to CIRC[ϕ; σ^*_m, σ^* v] by omitting auxiliary predicates, where σ^*_v and γ are auxiliary predicates introduced by Tr_v.

**Proof:** Let σ be the vocabulary of ϕ. Suppose τ = σ ∪ \{τ\} and τ_i = σ_m ∪ σ^*_v ∪ \{τ\}. Suppose τ-structure \mathfrak{B} and σ-structure \mathfrak{A} have the same interpretation on σ, defined in the same domain D.

First, we suppose that \mathfrak{A} is a σ-structure satisfying CIRC[ϕ; σ^*_m, σ^*_v]. Let \mathfrak{B} interpret γ to \mathfrak{T} and every Q' in σ^*_v to a relation filled up with D. In other words, for every Q' \in σ^*_v, \forall\bar{x}(Q'(\bar{x}) and γ are always valid in the interpretation of \mathfrak{B}. Now we need to show that \mathfrak{B} satisfies SM[Tr_v(ϕ; σ_m; σ_v; τ_i)]. It is not difficult to check \mathfrak{B} satisfies Tr_v(ϕ; σ_m; σ_v) (shortly, π(ϕ)).

To obtain a contradiction, we assume that \mathfrak{B} is not a model of SM[π(ϕ); τ_i]. Suppose that an assignment β satisfies both τ^*_i < τ_i and St(ϕ(β; τ_i)). In this assumption, we assert that β satisfies σ^*_m < σ_m. Otherwise, σ^*_m = σ_m implies that for all P^* \in σ^*_m, ∀\bar{x}(P^*(\bar{x}) ∨ \neg P(\bar{x})) are true. Next, β satisfies γ^* \iff ∀\bar{x}(P^*(\bar{x}) ∨ \neg P(\bar{x})) and γ^* should be assigned to τ_i. Then for each Q^* \in σ^*_v, Q^*(\bar{x}) is valid due to St((7); τ_i). As mentioned above, τ^*_i = τ_i is satisfied by β and it breaks the assumption, so the assertion is true.

Since β satisfies σ^*_m < σ_m, there is at least a predicate variable P^* \in σ^*_m, dissatisfying ∀\bar{x}(P^*(\bar{x}) ∨ \neg P(\bar{x})). Hence γ^* is assigned to \bot by β. Moreover, ∀\bar{x}(γ^* ∨ Q^*(\bar{x})) are valid and actually Q^* can change arbitrarily in the domain. Note that β satisfies St(P(\bar{x}) → τ_i) iff β satisfies \neg P^*(\bar{x}). According to the substitution method and the NNF of ϕ, it is clear that if β(σ^*_m) = β(σ_v), β satisfies St(ϕ; τ_i) iff β satisfies ϕ(σ^*_m, σ^*_v). Thus β satisfies ϕ(σ^*_m, σ^*_v) in \mathfrak{B}.

Let α be an assignment obtained by restricting β to variables in σ^*_m and let σ^*_v in α be the same as σ^*_v in β. So α satisfies σ^*_m < σ_m and ϕ(σ^*_m, σ^*_v) in \mathfrak{A}. No doubt that this conclusion implies that \mathfrak{A} is not a model of CIRC[ϕ; σ^*_m, σ^*_v] and makes a contradiction. So \mathfrak{B} is a model of SM[π(ϕ); τ_i].

Conversely, we suppose that \mathfrak{B} is a σ-structure satisfying SM[π(ϕ); τ_i]. Then we want to prove that \mathfrak{A} is a model of CIRC[ϕ; σ^*_m, σ^*_v]. Since \mathfrak{B} satisfies the formula ϕ^~m with a vocabulary of σ, ϕ is satisfied by \mathfrak{A}. Because for all P \in σ_m, the formulas ∀\bar{x}(P(\bar{x}) ∨ \neg P(\bar{x})) are always true, γ is interpreted to \mathfrak{T} by \mathfrak {B}. Furthermore, all Q'(\bar{x}) s.t. Q' \in σ^*_v are valid in \mathfrak{B} in that γ → Q'(\bar{x}) is satisfied.

Using reductio ad absurdum, we assume that α, an assignment in \mathfrak{A}, satisfies both σ^*_m < σ_m and ϕ(σ^*_m, σ^*_v). Let β be an assignment in \mathfrak{B} s.t. β(σ^*_m) = α(σ^*_m) and β(γ) = \bot. Due to the interpretation for σ^*_m in \mathfrak{B}, whatever predicate variables in σ^*_m are assigned to, β satisfies σ^*_m ≤ σ^*_v. Obviously it is true that τ^*_i < τ_i in β. It is clear that β satisfies St(ϕ^~m) iff \mathfrak{B} satisfies ϕ. Thanks to σ^*_m < σ_m, there is at least a predicate variable P^* \in σ^*_m, letting ∀\bar{x}(P^*(\bar{x}) ∨ \neg P(\bar{x})) be false and St((6); τ_i) is satisfied by β. In addition, β satisfies St((7); τ_i) and predicate variables Q^* can change arbitrarily in the domain. Now we let β assign Q^* in σ^*_v as same as Q^* in σ^*_v assigned by α. As ϕ is in NNF without implication, by a simple induction on formula structure, it is proved that β satisfies St(ϕ; τ_i) iff ϕ(σ^*_m, σ^*_v) is satisfied by β. According to the above conclusion, we can assume that β satisfies τ^*_i < τ_i and St(π(ϕ); τ_i). Since a contradiction is obtained, we can know that \mathfrak{A} is a model of CIRC[ϕ; σ^*_m, σ^*_v].

As for translation Tr_v, the number of auxiliary predicates introduced is one more than that of the varying predicates, which is acceptable and reasonable. Compared with the size 3 of the original sentence, the number of minimized and varying predicates is generally so small that the increased size resulting from them is considered insignificant. Thus translation Tr_v actually doubles the original size.

**Conjunction of Parallel Circumscriptions**

When it comes to encoding problems using the conjunction of parallel circumscriptions, generally we need to compute them one by one. There seems to be no way to substitute a single parallel circumscription for the conjunction of parallel circumscriptions, except for some special cases corresponding to the same FO sentence and the same tuple of varying predicates. Fortunately, based on the Splitting Theorem in SM-semantics (Ferraris et al. 2009), we can integrate conjunction of parallel circumscriptions into a FO theory under SM-semantics over arbitrary structures and then compute it at one time.

**Definition 2** Let φ_1, ..., φ_k be FO sentences in NNF, σ_1, ..., σ_k be mutually disjoint tuples of distinct predicates, and σ^*_v, ..., σ^*_v are tuples of arbitrary predicates. Then let Tr^*(ϕ; σ; σ^*_v) denote the conjunction of below formulas:

\[ \bigwedge_{1 \leq j \leq k} (\overline{\phi_j}) \quad (8) \]

\[ \bigwedge_{1 \leq j \leq k} (\forall P \in σ^*_v \quad \forall\bar{x}(P(\bar{x}) \lor \neg P(\bar{x}))) \quad (9) \]

\[ \bigwedge_{1 \leq j \leq k} (\forall Q^j(\bar{x}) \quad (10) \]

where \overline{ϕ_j} is obtained from ϕ_j in definition 1 by additionally substituting \neg P(\bar{x}) for each positive literal P(\bar{x}) if P in σ_i (i ≠ j) occurs in ϕ_j, \overline{ϕ}_j is obtained from ϕ_j by substituting: (i) (P(\bar{x}) → γ_j) for each negative literal \neg P(\bar{x}) s.t.

---

1 Without confusion, predicates as parameters are omitted.
2 To take no account of the interpretation of auxiliary predicates, we use \exists P\psi represent the formula obtained from ψ by substituting predicate variable P for predicate constant P.
\[ P \in \sigma_j, \text{(ii)} \neg P(\bar{x}) \text{ for each positive literal } P(\bar{x}) \text{ if } P \text{ in } \sigma_i(i \neq j), \text{ and (iii) } Q^j(\bar{x}) \text{ for each positive literal } Q(\bar{x}) \text{ and } (Q^j(\bar{x}) \rightarrow \gamma_j) \text{ for each negative literal } \neg Q(\bar{x}) \text{ s.t. } Q \in \sigma_i^j; \text{ and } \delta_i \text{ denotes the tuple of } Q^i \text{ for the } j \text{-th sentence.}

Translation \( T_{r^*} \) actually applies translation \( T_{rv} \) to each FO sentence respectively with a little modification. To avoid the strictly positive\(^5\) occurrences of intensional predicates, translation \( T_{r^*} \) adds \( \neg \) in front of those minimized predicates occurring in other sentences. Intuitively, \( \gamma_j \) reflects the minimization of the \( j \)-th circumscription.

**Proposition 2** Let \( \varphi_o \) be \( k \) FO sentences in \( \text{NNF} \), \( \sigma_o \) be \( k \) mutually disjoint tuples of distinct predicates, and \( \sigma^o_\varphi \) be \( k \) tuples of arbitrary predicates. Then \( \exists \sigma_o \forall \gamma_o \text{SM}[T_{r^*}(\varphi_o; \sigma_o; \sigma^o_\varphi); \sigma_o, \delta_o, \gamma_o] \text{ is equivalent to } \bigwedge_{1 \leq j \leq k} \text{CIRC}[\varphi_j; \sigma_j; \sigma^j_\varphi] \text{ by omitting auxiliary predicates.}

**Proof (sketch)** Using translation \( T_{rv} \) with a little modification, we can translate each CIRC[\( \varphi_j; \sigma_j; \sigma^j_\varphi \)] into a FO sentence under \( \text{SM-} \) semantics, shortly denoted by \( T_{rv}(\varphi_j) \). Because \( \varphi_j \) is in \( \text{NNF} \) without implication, in the predicate dependency graph\(^5\) of \( T_{rv}(\varphi_j) \), there is no edge being introduced by \( \neg Q^j \) and \( \neg \) except for subformulas in form of \( (P \rightarrow \gamma_j) \). According to the construction rule of predicate dependency graph, formula (6) \( \bigwedge_{1 \leq j \leq k} \text{CIRC}[\varphi_j; \sigma_j; \sigma^j_\varphi] \) introduces no edge. Next, those subformulas \( (P \rightarrow \gamma_j) \) in \( \varphi_j \) only introduce edges from \( \gamma_j \) to \( P \). In addition, formula (7) \( \bigwedge_{1 \leq j \leq k} \text{CIRC}[\varphi_j; \sigma_j; \sigma^j_\varphi] \) only introduces edges from auxiliary predicates in \( \delta_j \) to \( \gamma_j \). Therefore, strongly connected component can only occur in \( \delta_j \cup \{\gamma_j\} \). In accordance with the substitutions of \( \neg \) in \( T_{r^*} \), predicates in \( \sigma_j \) have no strictly positive occurrence in \( \varphi^j \), and \( \varphi^j \) s.t. \( i \neq j \). Additionally, all auxiliary predicates of \( \varphi_j \) are newly introduced, they cannot occur in other sentences. Indeed, with the preconditions of the Splitting Theorem satisfied, \( \bigwedge_{1 \leq j \leq k} \text{SM}[T_{r^*}(\varphi_j); \sigma_j, \delta_j, \gamma_j] \) is equivalent to \( \text{SM}[T_{r^*}(\varphi_o; \sigma_o; \sigma^o_\varphi); \sigma_o, \delta_o, \gamma_o] \). So this proposition is proved and shows translation \( T_{r^*} \) is faithful. \( \blacksquare \)

**Prioritized Circumscription**

Next, we further consider the computation of prioritized circumscription via converting it into a FO theory under \( \text{SM-} \) semantics. Indeed, a prioritized circumscription can be represented by the conjunction of parallel circumscriptions, which was presented by Proposition 15 in (Lifschitz 1994): CIRC[\( \varphi; \sigma_1 > \ldots > \sigma_k; \sigma_\varphi \)] is equivalent to the conjunction of CIRC[\( \varphi; \sigma_j \bigcup_{1 \leq j \leq k} \sigma_j \bigcup_j \sigma^j_\varphi \)] s.t. \( 1 \leq j \leq k \).

Based on translation \( T_{r^*} \), we can integrate parallel circumscriptions as conjuncts to compute a prioritized circumscription at a time rather than at \( k \) times. Because all priorities of minimized predicates are disjoint, translation \( T_{r^*} \) can be applied to compute prioritized circumscription, shown in Example 2. Besides, these parallel circumscriptions share the same FO sentence \( \varphi \), so there is only one \( \varphi^\sim \) in the resulting sentence. Further we can adapt translation \( T_{r^*} \) to compute the conjunction of prioritized circumscriptions.

---

\(^{5}\)For space limitations, please refer to (Ferraris et al. 2009).

Next we analyze translation \( T_{r^*} \) applied to prioritized circumscription. Suppose that there are \( m_j \) minimized predicates in \( j \)-th priority and \( n \) varying predicates. Then the number of auxiliary predicates introduced is \( \sum_{j=1}^{k}(j - 1)m_j + k(n + 1) \). Because the size of the original sentence is much greater than the number of minimized and varying predicates, translation \( T_{r^*} \) expands into \( k + 1 \) times in size.

**Example 2** For CIRC[\( \varphi; Ab_1 > Ab_2; Pacifist^1 \)] in Example 1, by applying \( T_{r^*} \), we can get a sentence under SM-semantics. Here only show the result for 1st priority \{\( Ab_1 \)\}:\n
\( \neg \text{Quaker}(x) \lor \text{Ab}_1(x) \lor \text{Pacifist}^1(x) \) (11)
\( \neg \text{Republican}(x) \lor \text{Ab}_2(x) \lor (\text{Pacifist}^1(x) \rightarrow \gamma_1) \) (12)
\( \gamma_1 \leftrightarrow \forall x(\text{Ab}_1(x) \lor \neg \text{Ab}_1(x)) \) (13)
\( \gamma_1 \rightarrow \text{Pacifist}^1(x) \land \text{Ab}_2(x) \) (14)

**Optimization and Computation**

In the above section, we introduce translations from general FO circumscription into FO theories under stable model semantics over arbitrary structures. According to (Cabalar and Ferraris 2007), every sentence in PNF without existential quantifiers under SM-semantics can be translated easily into ASP. However, because of the arbitrariness of FO sentence, it is essential to eliminate existential quantifiers.

**Optimization in Elimination Existential Quantifiers**

With Zhang’s reduction (Zhang et al. 2011), existential quantifiers in SM-semantics can be eliminated over finite structures. Based on his approach, we propose an optimization to introduce fewer auxiliary predicates and downsize logic programs when eliminating existential quantifiers during translating general circumscription to ASP.

**Definition 3** Let \( \varphi \) be a FO sentence in PNF of the form \( \forall \exists \exists \exists \vartheta(x, y) \) where \( \vartheta \) is quantifier-free in PNF, and we define optimization \( \Gamma_2(\varphi; \sigma_m; \sigma_\varphi) \) to be the conjunction of below formulas with universal quantifiers omitted:

\( \neg S(\bar{x}, \text{mmm}) \) (15)
\( (\text{succ}(\bar{y}, \bar{y}')) \land S(\bar{x}, \bar{y}')) \lor \vartheta^\sim(\bar{x}, \bar{y}) \rightarrow S(\bar{x}, \bar{y}) \) (16)
\( (\text{succ}(\bar{y}, \bar{y}')) \land W(\bar{x}, \bar{y}')) \lor \vartheta^\top(\bar{x}, \bar{y}) \rightarrow W(\bar{x}, \bar{y}) \) (17)
\( T(\bar{x}, \text{mmm}) \lor \vartheta(\bar{x}, \text{mmm}) \) (18)
\( \text{succ}(\bar{y}, \bar{y}') \rightarrow (T(\bar{x}, \bar{y}) \leftrightarrow \vartheta(\bar{x}, \bar{y}') \lor T(\bar{x}, \bar{y}')) \) (19)
\( \{(\text{succ}(\bar{y}, \bar{y}) \land \neg W(\bar{x}, \bar{y}')) \lor \bar{y} = \text{max} \} \land W(\bar{x}, \bar{y}) \rightarrow T(\bar{x}, \text{max}) \leftrightarrow \vartheta(\bar{x}, \bar{y}) \) (20)
\( \gamma \rightarrow \forall \bar{z}(P(\bar{x}) \lor \neg P(\bar{x})) \) (21)
\( \bigwedge_{Q' \in \sigma_m} \forall \bar{z}(\gamma \rightarrow Q'(\bar{x})) \) (22)

where \( \vartheta^\sim \) and \( \vartheta \) are obtained from \( \varphi^\sim \) and \( \varphi \) respectively in Definition 1; \( \vartheta^\top \) is obtained from \( \vartheta \) by substituting: (i) \( \top \) for each positive literal \( Q(\bar{x}) \) s.t. \( Q \in \sigma_\varphi \), and for each negative literal \( \neg P(\bar{x}) \) s.t. \( P \in \sigma_m \cup \sigma_\varphi \), (ii) \( \neg \neg P(\bar{x}) \) for each positive literal \( P(\bar{x}) \) s.t. \( P \in \sigma_m \); succ is a successor relation on
the domain based on a total order; \( \text{max} \) and \( \text{min} \) denote the maximum and minimum tuple on the successor relation respectively; \( S, T, W, \gamma, \) and \( \sigma_o \) are auxiliary predicates.

Optimization \( \Gamma_3 \) integrates translation \( Tr_o \) and Zhang’s reduction from general FO parallel circumscription to FO theories under SM-semantics. Now there are two ways which differ in the first step to eliminate the first block of continuous existential quantifiers. The first way calls Zhang’s reduction after applying \( Tr_o \) while the second uses \( \Gamma_3 \). Next both ways use Zhang’s reduction repeatedly till eliminating all existential quantifiers.

After the first step, the second way introduces one fewer auxiliary predicate than those introduced by the first way. Besides, suppose the size of the original sentence is \( n \), then the result of the first way is \( 8 \times n \), while that of the second is \( 5 \times n \). With iterations increasing, the size grows rapidly. Eventually, \( \Gamma_3 \) reduces logic programs in size by one third.

We can easily generalize \( \Gamma_3 \) with \( Tr_o \) for prioritized circumscription, which is analyzed in the next section.

Computing Circumscription via ASP

The above translations and optimization actually can be applied to each conjunct of the original sentences, so they can be applied more flexibly. For example, \( \text{CIRC} [\exists y \vartheta(\bar{y}) \land \varphi] \) is equivalent to \( \text{SM}[\exists y \vartheta(\bar{y})] \land Tr_o(\varphi) \).

Eventually, fixed and varying predicates are treated as extensional predicates in SM-semantics rather than being removed from the formula. Extensional predicates can be handled easily in ASP, by introducing \( \forall \bar{x} (P(\bar{x}) \lor \neg P(\bar{x})) \) (Ferraris, Lee, and Lifschitz 2011). To sum up, we can compute parallel circumscription with varying predicates by 4 steps:

1. Turn the input into the sentence in both PNF and NNF;
2. Apply \( Tr_o \) or \( \Gamma_3 \) to get a theory under SM-semantics;
3. Use Zhang’s reduction repeatedly till obtaining ASP;
4. Add \( \forall \bar{x} (P(\bar{x}) \lor \neg P(\bar{x})) \) for each fixed/varying predicate.

With the similar method, we can generalize the computation to suit prioritized circumscription.

Remark 1 As for the above translations, we have not mentioned function constants and individual constants, because for each \( n \)-arity function we can introduce a \( n+1 \)-arity predicate to represent it. Precisely, \( \exists y P_f(\bar{x}, y) \) can simulate \( f(\bar{x}) \) with a restriction of \( \neg(P_f(\bar{x}, y) \land P_f(\bar{x}, z) \land y \neq z) \). We can use such predicates rather than functions as varying constants. Particularly, varying individual constants can be simulated by existential quantifiers.

Some Experimental Results

We developed a general FO circumscription solver \text{cfo2lp}^6. \text{cfo2lp} firstly accepts a circumscription, then translates it into a logic program, and finally invokes an ASP solver with a finite extensional database. To compare \text{cfo2lp} with a propositional circumscription solver \text{circ2dlp}^8 and an ASP solver supporting inclusion-based minimization \text{metasp}^9, we use circuit diagnosis problem (CDP) and extended stable marriage problem (ESMP) as benchmarks.

Circuit Diagnosis Problem

According to (Reiter 1987; Besnard and Cordier 1994), CDP is stated: given a circuit and its observation, find a minimal explanatory diagnosis, which is a set of error components.

We use a \( n \)-bit ripple adder as our circuit consisting of \( n \) full adders which include and gate, xor gate, and or gate. Let \( I_1 \) and \( I_2 \) be the inputs and \( O \) be the output of the gate. Then we can use FO sentence \( \varphi \) to represent the total ripple adder and the observation of its inputs and outputs. Based on engineering experiences, different kinds of circuit component have different error probability. Intuitively, we can assign a higher priority in circumscription to the components of lower error probability. Suppose that and gate is more likely in error than xor and so is xor than or. We can obtain a minimal explanatory diagnosis \( \Delta \) iff \( \Delta \) is a model of \( \text{CIRC}[\varphi; Ab_o > Ab_x > Ab_o; I_1, I_2, O] \).

Extended Stable Marriage Problem

According to (Mairson 1992), the stable marriage problem is the problem of finding a stable match between men and women given their respective preference list. Let block pair represent a pair of man and woman who are not partners, both prefer each other to their current partners in the match. A match is stable if it contains no block pair. (Iwama et al. 1999) extended it with both incomplete lists and ties, making the complexity become NP-hard.

Based on Iwama et al.’s extension, we further extend it with “satisfaction” to make it more realistic in practice. With this notion, we aim to find optimal stable marriages which there are as few as possible people unsatisfying. Next, we represent our extension with prioritized circumscription. To represent the preference lists, let \( \text{Grade}(x, p, y) \) denote person \( x \) grades person \( y \) with a natural number \( p \). Let \( H_1(x) \) denote that the current partner of a person \( x \) is graded by \( x \) with a grade not exceeding one third of the number of pairs, which is considered that \( x \) is unsatisfied with the match extremely. Similarly, we define \( H_2(x) \) to represent \( x \) is somewhat unsatisfied, if the grade is in the intermediate third. To get the minimality of extremely unsatisfied people and secondly somewhat unsatisfied people, we compute the circumscription with the priority of \( H_1 > H_2 \). We can use a FO sentence \( \varphi \) with existential quantifiers to describe ESMP naturally. By computing \( \text{CIRC}[\varphi; H_1 > H_2; \text{Partner}] \), the interpretation of Partner is regarded as a solution.

Experimental Results

Table 1 (Table 2) shows the performance comparisons among \text{cfo2lp}, \text{circ2dlp} and \text{metasp} scale up, when the number \( n \) of gates in the ripple adder (persons in ESMP) grows. Real numbers in the tables figure the run time (in seconds) of solvers to compute circumscription. If the time exceeds one

---

7An extensional database is a structure consisting of extensional predicate and function constants under SM-semantics.
8circ2dlp. http://www.tcs.hut.fi/Software/circ2dlp/
hour, we simply write it as “−”. All experiments run on a PC with AMD A10-5800K 3.8GHz CPU on Linux Ubuntu 13.04. Each instance was randomly generated, which was computed five times and taken the average by calling the same ASP solver claspD10 as back-end.

Actually, cfo2lp and metasp have comparative performances which are better than those of circ2dlp in CDP. While in ESMP, metasp has the best performance and cfo2lp is ranked second because of the big size of logic program resulting from existential quantifiers.

To analyze optimization $\Gamma_3$ for prioritized circumscription, we remove the optimization from cfo2lp and implement cfo2lp* (in Table 2). As its performances show, optimized logic programs can save 10-60% time cost.

Indeed, experimental results show that our approach can solve problems represented by circumscription effectively.

Applications

This section applies cfo2lp to DLs with circumscription and finding minimal repairs in inconsistent databases, both of which can be handled effectively.

Description Logics with Circumscription

To extend DLs with non-monotonic features, (Bonatti, Lutz, and Wolter 2006) proposed that parallel and prioritized circumscription can be used in a straightforward and transparent way for modelling defeasible inheritance.

Example 3 [Example in (Bonatti, Lutz, and Wolter 2006)]

\[
\begin{align*}
\text{Mammal} & \sqsubseteq \exists \text{habitat.Land} \sqcap Ab_M \\
\text{Whale} & \sqsubseteq \text{Mammal} \sqcap \neg \exists \text{habitat.Land}
\end{align*}
\]

(23)

(24)

Indeed, concept $Ab_M$ can be regarded as abnormality of mammals. Intuitively, mammals normally live on land and whales are mammals not inhabiting land. We can use different circumscription policies to obtain different assertions of concepts. One is only circumscribing the abnormality predicates by computing $\text{CIRC}[(23) \land (24); Ab_M]$.

However, this policy is too strong, because all concepts except abnormality predicates, such as $\text{Whale}$, have no any change actually and it is not natural and intuitive for finding more exact and smaller inclusions. When we vary concept $\text{Land}$ and role $\text{Habitat}$ freely and compute $\text{CIRC}[(23) \land (24); Ab_M; \exists \text{habitat.Land}]$, we can conclude that mammals are almost likely to live on land except for whales.

By applying our approach to such DLs, we can obtain assertions of all concepts and roles of all minimal models as the computation result, which provides a reference in Herbrand models over a fixed set of individuals.

Reparis in Inconsistent Databases

Barceló and Bertossi (2003) represented a repair, which minimally modifies inconsistent database instances, by an ASP program. A repair program encodes function dependency with the restriction on a FO sentence without existential quantifiers. Bertossi (2011) further generalized repairs with prioritized circumscription, in such order: database predicates, predicates with annotation, and query predicates. Using our approach, we can relax the restriction of function dependency to allow true FO quantifiers. By our approach, we can find all minimal repairs in inconsistent databases.

Related Work and Discussions

In (Cadoli, Eiter, and Gottlob 1992), varying predicates can be complied away only in inference which decides whether a formula is entailed by a circumscription, but we are more interested in finding all minimal models. To find all models, we consider all interpretations of varying predicates because they would make structures different.

An embedding of FO circumscription in SM-semantics has been shown in (Zhang et al. 2011), but it forbids constants to vary. However, the policy of circumscription forbidding varying predicates is often too strong for many applications, such as Example 3. It is more natural and intuitive to allow varying constants when finding more exact and smaller models. Besides, our approach can integrate parallel circumscriptions to compute them at one time, even further generalized to prioritized circumscription.

There is a choice between encoding naturalness and computation efficiency, circ2dlp (Oikarinen and Janhunen 2008) can compute prioritized circumscription in the propositional case and metasp (Gebser, Kaminski, and Schaub 2011) can find inclusion-based minimal answer sets in extended logic programs under a priority order. They both may need an unintuitive and complicated input. However, we focus on encoding naturalness rather than computation efficiency. With the true FO quantifiers, we can represent problems naturally and succinctly. Besides, for problems which need to be encoded with existential quantifiers, such as ESMP, an exponential expansion in size probably occurs so that the computation may become intractable in circ2dlp. For these problems, metasp represents them with constraints instead of existential quantifiers and computes more efficiently. While cfo2lp may cause a logic program of big size resulting from existential quantifiers which affects the efficiency.

In many applications, we can take advantage of FO quantifiers and represent problems more naturally and
succinctly. For an ASP layman, compared with other efficient ASP-based solvers, it is easier to use FO circumscription to represent problems. Our approach can close the gap between representation naturalness and computation efficiency.

### Conclusion

The relationship between FO circumscription and FO theories under SM-semantics has been clarified in this paper. Furthermore, we proposed and proved linear translations from general FO parallel and prioritized circumscription to FO theories under SM-semantics over arbitrary structures. Based on the translations, all minimal models of FO theories can be computed effectively via ASP solver. Our approach is not only theoretically interesting but of practical relevance. We can apply it to compute minimal models in DLs with circumscription and minimal repairs in inconsistent databases.

Now we summarize the contributions of this paper. First, we proposed a practically available framework of computation for general FO parallel and prioritized circumscription with varying constants over finite structures, which builds a bridge between circumscription and theories under SM-semantics. Secondly, based on a total order, we optimized the elimination of existential quantifiers to figure out practical problems represented by general circumscription and developed a solver \texttt{cfo2lp}. Finally, allowing true FO quantifiers, varying constants, and priorities in circumscription provides a flexible and natural way to represent problems so that our approach can be applied in more fields.
