Deterministic Performance Bounds on the Mean Square Error for Near Field Source Localization

Mohammed Nabil El Korso, Alexandre Renaux, Rémy Boyer, and Sylvie Marcos

Abstract—This correspondence investigates lower bounds on estimator’s mean square error applied to the passive near field source localization. More precisely, we focus on the so-called threshold prediction for which these bounds are known to be useful. We give closed form expressions of the McAulay-Seidman, the Hammersley-Chapman-Robbins, the McAulay-Hofstetter bounds and also, a recently proposed bound, the so-called Todros-Tabrikian bound, for the deterministic observation model (i.e., parameterized mean) and the stochastic observation model (i.e., parameterized covariance matrix). Finally, numerical simulations are given to assess the efficiency of these lower bounds to approximate the estimator’s mean square error and to predict the threshold effect.

Index Terms—Deterministic lower bounds, mean square error, near field source localization, performance analysis, threshold prediction.

I. INTRODUCTION

Source localization is an important and challenging topic with several applications such as sonar, seismology, digital communications, etc. Particularly, the context of far field sources has been widely investigated in the literature and a plethora of algorithms to estimate localization parameters have been proposed [1]. In this case, the sources are assumed to be far from the array of sensors. Consequently, the propagating waves are assumed to have planar wavefront. However, when the sources are located in the so-called near field region, the curvature of the waves impinging on the sensors can no longer be approximated. Therefore, in this scenario, each source is characterized by its bearing and its range (distance between the source and a reference sensor). One can note the existence of some estimation algorithms adapted to the passive near field source localization [2]–[6].

Nevertheless, there exist only few works studying the asymptotic estimation performance in this context [4], [7] (by asymptotic we mean a large signal to noise ratio or a large number of snapshots [8], [9]). More precisely, to characterize the asymptotic performance of an estimator in terms of the mean square error, the Cramér-Rao bound, is a tight bound under certain mild/general conditions [10], is the most popular tool [11]. However, the Cramér-Rao bound becomes too optimistic in the non-asymptotic region (i.e., when the outlier effect appears [12], [13]). This non-asymptotic region is delimited by the so-called threshold or breakdown point (i.e., when the estimator’s mean square error increases dramatically.) One should note that the prediction of this threshold is of great importance since it delimits the optimal operating zone of the estimators.

To fill this lack, some other minimal bounds tighter than the Cramér-Rao bound has been proposed. In [14]–[17] the authors provide a different unification of some well known lower bounds on the mean square error of unbiased estimators of deterministic parameters. More precisely, in [16], Forster and Larzabal, solved the problem of establishing lower bounds on the mean square error for one deterministic parameter estimation using a constrained optimization problem. By imposing some adequate constraints on the bias for the considered optimization problem, they have rediscovered several lower bounds as the Cramér-Rao, the Barankin and the Bhattacharyya bounds. The extension to several unknown deterministic parameters can be found in [17]. In [14], Todros and Tabrikian propose a new class of performance lower bounds using the so-called integral transform which generalizes the derivative applied on the likelihood-ratio function. Thus, they showed that some well known lower bounds (as the Cramér-Rao, the McAulay-Seidman and the Bhattacharyya bounds) are obtained by a proper choice of the kernel of the integral transform of the likelihood-ratio function. It can be noted that the limiting expression (w.r.t. test points) of some of these lower bounds leads to the Barankin bound [18]. This bound is considered as the greatest lower bound on the mean square error of any unbiased estimator [17]. Unfortunately, the Barankin bound is the solution of an integral equation with an incomputable analytic solution.

To the best of our knowledge, no results can be found in the literature concerning the threshold prediction in the context of near field source localization1. In this correspondence, we fill this lack. We consider the two classical source signal model assumptions [9]: the deterministic model (i.e., when the signals are assumed to be deterministic) and the stochastic model (i.e., when the signals are assumed to be driven by a Gaussian random process). Furthermore, in both cases, the observation model is corrupted by a spatially colored noise. For each model, we propose to characterize the threshold region using some deterministic lower bounds on the estimator’s mean square error (i.e., lower bounds w.r.t. unknown deterministic parameters of interest). In particular, we derive and analyze the following deterministic lower bounds: the McAulay-Seidman [20], the Hammersley-Chapman-Robbins [21], [22], the McAulay-Hofstetter [23] bounds and also, a new proposed bound, the so-called Todros-Tabrikian bound [14].

This correspondence is organized as follows. Section II formulates the problem and basic assumptions. In Section III we present the derivation of the lower bounds under the deterministic and stochastic assumption. Section IV is devoted to numerical analysis. Finally, conclusions are given in Section V.

II. MODEL SETUP

In the near field context, the waves impinging on the sensors are considered to be spherical. Consequently, the time delay $\tau_n$ associated with the signal propagation time from a referential sensor (let say the first one) to the $(n + 1)$th sensor is given by (see [4, Fig. 1] for the adequate labelling):

$$\tau_n = \frac{2\pi \tau}{\lambda} \left( \sqrt{1 + \frac{n^2 L^2}{r^2} - \frac{2nL \sin \theta}{r}} - 1 \right).$$

1Note that in [19] the authors analyzed only the stochastic signal model while both deterministic and stochastic signals models are analyzed in this paper. Moreover, the authors in [19] studied localization performance with $H$ distributed array of sensors. While, as mentioned by the authors, the source is near-field with respect to the overall “array of arrays”. However, the far-field approximation was considered with respect to each array. Our model corresponds to $H = 1$ and, in this case (only one array), the source cannot be considered in the far-field and in the near-field.
where $\lambda$ is the signal wavelength and where $r$ and $\theta \in [0, \frac{\pi}{2}]$ denote the range (i.e., the distance between the source and the referential sensor) and the bearing of the source, respectively. More precisely, when the source is located in the so-called Fresnel region [3], i.e., if 
\[
0.62 \left( \frac{d^3(N-1)^3}{\lambda^3} \right)^{\frac{1}{2}} < r < \frac{2d^2(N-1)^2}{\lambda},
\]
in which $N$ denotes the number of sensors. Then, the time delay (1) is given by: 
\[\tau_n = \omega n + \phi n^2 + O \left( \frac{a^2}{\lambda^2} \right),\]
where $O \left( \frac{a^2}{\lambda^2} \right)$ denotes the terms smaller or equal to $\frac{a^2}{\lambda^2}$, in which the so-called electrical angles are given by:
\[
\omega = -2\pi \frac{d}{\lambda} \sin(\theta),
\]
and
\[
\phi = \pi \frac{d^2}{\lambda r} \cos^2(\theta).
\]
Neglecting $O \left( \frac{a^2}{\lambda^2} \right)$, the time delay $\tau_n$ can be approximated by the following quadratic form
\[
\tau_n = \omega n + \phi n^2.
\]
Consequently, considering a uniform and linear array (ULA) composed of $N$ sensors with an inter-element spacing $d$, receiving a single near-field and narrowband source, the observation model is, then, given as follows [2]:
\[
\mathbf{x}(t) = [\mathbf{x}_1(t), \ldots, \mathbf{x}_N(t)]^T = a(\omega, \phi) \mathbf{v}(t) + \mathbf{v}(t), \quad t = 1, \ldots, T,
\]
where $\mathbf{v}(t)$ denotes the transpose sign and $T$ is the number of snapshots, whereas, $\mathbf{v}(t) = [v_1(t), \ldots, v_N(t)]^T$ and $x_n(t)$ is the observed signal at the output of the $(n+1)$th sensor. The source signal is denoted by $s(t)$. The random process $\mathbf{v}(t)$ is an additive noise. The $(n+1)$th element of the steering vector $a(\omega, \phi)$ is given by $a(\omega, \phi)_{n+1} = r^{-n} \omega n + \phi n^2$.

In the remain of this paper, we will use the following assumptions:
- The noise will be assumed to be a complex circular Gaussian process with zero mean with a known covariance (full rank) matrix $\mathbf{R}_{\mathbf{n}n} = \mathbf{E}[\mathbf{n}(t)\mathbf{n}(t)^H]$. For both deterministic [8] and stochastic [24] models, the unknown vector parameter is given by $\mathbf{c} = [\omega, \phi]^T$.
- The joint probability density function of the observations $\mathbf{X} = [\mathbf{x}(1), \ldots, \mathbf{x}(T)]^T \sim C_{N}(\mathbf{\mu}(\mathbf{c}), \mathbf{\Sigma}(\mathbf{c}))$ for a given $\mathbf{c}$, is expressed as:
\[
p(\mathbf{x}; \mathbf{c}) = \frac{1}{\pi^N} \left| \mathbf{E}[\mathbf{c}] \right|^N \exp[-(\mathbf{x} - \mathbf{\mu}(\mathbf{c}))^H \mathbf{\Sigma}(\mathbf{c})^{-1} (\mathbf{x} - \mathbf{\mu}(\mathbf{c}))],
\]
in which $|\cdot|$ denotes the determinate operator. Depending on the considered signal model we will specify, in the following, the structure of $\mathbf{\mu}(\mathbf{c})$ and $\mathbf{\Sigma}(\mathbf{c})$.

### III. Deterministic Lower Bounds Derivation

#### A. Background: Deterministic Lower Bounds Unification

The unification presented in [14] states that the mean square error (MSE) of any unbiased estimator can be lower bounded as follows:
\[
\text{MSE}(\hat{\mathbf{c}}) = E_{\mathbf{x}: \mathbf{c}} \left\{ (\hat{\mathbf{c}} - \mathbf{c}) (\hat{\mathbf{c}} - \mathbf{c})^H \right\} \geq \mathbf{C} = \mathbf{K}^{-1} \mathbf{C}^H
\]
with
\[
\mathbf{K} = E_{\mathbf{x}: \mathbf{c}} \left\{ \mathbf{\gamma} \mathbf{\gamma}^H \right\},
\]
where $\hat{\mathbf{c}}$ is the estimate of the true parameter $\mathbf{c}$, $E_{\mathbf{x}: \mathbf{c}} \{ \cdot \}$ is the expectation w.r.t. $p(\mathbf{x}; \mathbf{c})$, $\mathbf{C}$ is a lower bound matrix, $\mathbf{A} \preceq \mathbf{B}$ means that the matrix $\mathbf{A} - \mathbf{B}$ is non-negative defined. Consequently, it has been shown that for a specific choice of the couple $\{\mathbf{F}, \mathbf{\gamma}\}$, one obtains a specific lower bound. In this way, the Cramér-Rao bound (CRB) can be defined using the following couple:
\[
\left\{ \begin{array}{l}
\mathbf{\Gamma}_{\mathbf{CRB}} = \mathbf{I}_2, \\
\mathbf{\gamma}_{\mathbf{CRB}} = \mathbf{F}_{\mathbf{CRB}} \mathbf{c} \end{array} \right.,
\]
in which $\ln$ denotes the natural logarithm where $\mathbf{1}$, is the $l \times 1$ vector filled by ones. For the following couple:
\[
\left\{ \begin{array}{l}
\mathbf{\Gamma}_{\mathbf{MSB}} = \mathbf{\Phi}, \\
\mathbf{\gamma}_{\mathbf{MSB}} = [\nu(x; \xi_1), \ldots, \nu(x; \xi_L)]^T
\end{array} \right.,
\]
one obtains the McAulay-Seidman bound (MSB), in which the so-called ratio-likelihood function is given by:
\[
\nu(x; \xi_i) = \frac{p(x; \xi_i)}{p(x; \xi_0)},
\]
and where $\xi_i$ for $i = 1, \ldots, L$ denotes the L test points, whereas $\Phi = [\xi_1 - \xi_0, \ldots, \xi_L - \xi_0]$. The Hammersley-Chapman-Robbins bound (HCRB) can be defined using
\[
\left\{ \begin{array}{l}
\mathbf{\Gamma}_{\mathbf{HCRB}} = \mathbf{I}_2, \\
\mathbf{\gamma}_{\mathbf{HCRB}} = [\nu_c(\mathbf{c}), \nu^{(f)}(\mathbf{c})] \end{array} \right.,
\]
where $\Phi_c$ denotes the $2 \times 2$ identity matrix.

Recently, a new deterministic Cramér-Rao Fourier bound, called the Todros-Tabrikian bound (TTB), was proposed in [14]. To have a gain in computing time, this latter applies the discrete Fourier transform (DFT) on $\Phi$ and $\gamma_{\mathbf{MSB}}$. Consequently, it is given thanks to the following couple:
\[
\left\{ \begin{array}{l}
\mathbf{\Gamma}_{\mathbf{TTB}} = \mathbf{I}_2, \\
\mathbf{\gamma}_{\mathbf{TTB}} = \left[ \mathbf{\gamma}_{\mathbf{CRB}}, \mathbf{\gamma}_{\mathbf{HCRB}} \right]^T
\end{array} \right.,
\]
where $\mathbf{I}_2$ denotes the $2 \times 2$ identity matrix.
B. Deterministic Lower Bounds Matrix Expressions

After some straightforward calculation it can be shown (see [14, Appendix M]) that the TTB is expressed as

\[ C_{TBB}^{(r,p)} = C_{CRB} + QW^H \left( WRW^H \right)^{-1} WQ, \]

(17)

where

\[ Q = C_{CRB} D - \Phi, \]

(18)

in which

\[ D = [d(\xi_1) \ldots d(\xi_L)]. \]

(19)

and

\[ d(\xi_i) = -\left( \frac{\partial \text{KLD}(p(\chi; \xi_i))}{\partial \xi} \right) \lambda_k - E_{\xi_i} \]

(20)

where the KLD denotes the Kullback-Leibler divergence and

\[ R = \Psi - D^T C_{CRB} D \]

with \( [\Psi]_{m,n} = E_{\xi} \exp\left( r(\chi, \xi_m) \chi(\chi, \xi_n) \right) \)

where \( m = 1, \ldots, L, n = 1, \ldots, L. \)

(21)

Following the same methodology, one can easily obtain the following matrix expressions:

\[ C_{MHB}^{(r)} = \Phi \Phi^T, \]

(22)

\[ C_{MBH}^{(r)} = \Phi \left( \Psi - 1, 1^T \right)^{-1} \Phi^T, \]

(23)

\[ C_{MHB} = C_{CRB} + QR - Q^T. \]

(24)

In the following we give closed-form expressions of the elements of \( C_{MHB}^{(r)}, C_{MBH}^{(r)}, C_{MHB}^{(r)} \) and \( C_{TBB}^{(r,p)} \). We focus only on \( D \) and \( \Psi \), since the expression of \( C_{MBH} \) is well known, for which complex circular Gaussian observations (i.e., if \( \chi \sim CN(\mu(\xi_i), \Sigma(\xi_i)) \)) one has \( C_{MBH} = \text{FIM}^{-1} \) [25], where

\[
\text{FIM}_{i,k} = \text{tr} \left\{ \Sigma(\xi_i)^{-1} \left[ \frac{\partial \Sigma(\xi_i)}{\partial \xi_k} | \lambda_k - E_{\xi_i} \right] \right\} + 2 \Re \left\{ \frac{\partial \mu(\xi_i)^H}{\partial \xi_k} | \lambda_k - E_{\xi_i} \right\},
\]

(25)

in which \( \text{tr} \{ \cdot \} \) and \( \Re \{ \cdot \} \) denote the trace operator and the real part, respectively.

1) The Deterministic Case: In the deterministic case we assume that \( s(t) = \alpha(t) e^{j(2\pi ft + \psi(t))} \) is the source signal with a carrier frequency equal to \( f_c \), where \( \alpha(t) \) and \( \psi(t) \) are the known real amplitude and the known shift phase, respectively. Consequently, one has an observation model with a parameterized mean such that \( \chi \sim CN(\mu(\xi_i), \Sigma(\xi_i)) \) where \( \mu(\xi_i) = [s(1) a^H(\omega_0, \phi_0) \ldots s(T) a^H(\omega_0, \phi_0)]^T. \) Then, by applying (25) one has

\[ \text{FIM}_{i,k} = 2 \Re \left\{ \frac{\partial \mu(\xi_i)^H}{\partial \xi_k} | \lambda_k - E_{\xi_i} \right\}, \]

\[ i = 1, 2, k = 1, 2. \]

(26)

Furthermore, one obtains:

\[ \text{KLD}(p(\chi; \xi_i) | p(\chi; \xi_i)) = - \int_{C^{NT}} p(\chi; \xi_i) \left[ \chi - \mu(\xi_i) \right] H \Sigma^{-1} \left[ \chi - \mu(\xi_i) \right] d\chi \]

\[ = \int_{C^{NT}} \left[ \chi - \mu(\xi_i) \right] H \Sigma^{-1} \left[ \chi - \mu(\xi_i) \right] p(\chi; \xi_i) d\chi \]

\[ = \int_{C^{NT}} \left[ \chi - \mu(\xi_i) \right] H \Sigma^{-1} \left[ \chi - \mu(\xi_i) \right] d\chi \]

\[ = (\mu(\xi_i) - \mu(\xi_i))^H \Sigma^{-1} (\mu(\xi_i) - \mu(\xi_i)). \]

(27)

The term KLD \( (p(\chi; \xi_i) | p(\chi; \xi_i)) \) and (20)–(21) lead to: (see the equation at the bottom of the page), in which

\[ \alpha(\xi_m, \xi_n) = \exp(-2 \Re \mu(\xi_m)^H \Sigma^{-1} \mu(\xi_n) - \mu(\xi_m)^H \Sigma^{-1} \mu(\xi_n)) \]

\[ + \mu(\xi_m)^H \Sigma^{-1} \mu(\xi_n) + \mu(\xi_m) \mu(\xi_n) \]

\[ = \exp\left( \mu(\xi_m) - \mu(\xi_n) \right) H \Sigma^{-1} \left( \mu(\xi_m) - \mu(\xi_n) \right) \}

(28)

Finally, \( C_{MHB}^{(r)}, C_{MBH}^{(r)}, C_{MHB}^{(r)} \) and \( C_{TBB}^{(r,p)} \) are given by plugging (26), (27) and (28) into (24), (23), (22) and (17), respectively. See Appendix A for non-matrix expressions of \( C_{TBB}^{(r)} \) (i.e., in the case where \( P = 1 \)).

2) The Stochastic Case: Let us consider the stochastic model, i.e., when the signals are assumed to be Gaussian (with zero mean and variance \( \sigma^2 \)) independent of the noise. Under this assumption, one obtains an observation model with a parameterized covariance matrix such that \( \chi \sim CN(0, \Sigma(\xi_i)) \) where the covariance matrix \( \Sigma(\xi_i) \) is of the form

\[ \Sigma(\xi_i) = \sigma^2(I_T \otimes \text{Re}[a(\omega_0, \phi_0)]^H(\omega_0, \phi_0) + \Sigma_{\text{noise}} \}

(29)
First, note that:

\[ \text{KLD} \left( p(x; \xi_n) \| p(x; \xi) \right) \]
\[ = \int_{\mathbb{C}^N} p(x; \xi_n) \ln \frac{p(x; \xi_n)}{p(x; \xi)} \, dx \]
\[ = \int_{\mathbb{C}^N} \frac{1}{\pi^{N/2} |\Sigma(\xi_n)|} \left( \chi^H (\Sigma(\xi_n)^{-1} - \Sigma(\xi)^{-1}) \chi \right) \]
\[ \times \exp \left( -\chi^H \Sigma(\xi)^{-1} \chi \right) \, dx \]
\[ = E_{x \sim \mathcal{N}} \left\{ \chi^H \Sigma(\xi) \chi \right\} + E_{x \sim \mathcal{N}} \left\{ \chi^H \Sigma(\xi_n) \chi \right\} + \text{Ln} \frac{|\Sigma(\xi)|}{|\Sigma(\xi_n)|} \quad (30) \]

Observing that:

\[ E_{x \sim \mathcal{N}} \left\{ \chi^H \Sigma(\xi) \chi \right\} \]
\[ = \sum_{i=1}^{N} \sum_{j=1}^{N} E_{x \sim \mathcal{N}} \left\{ |x_{i,j}|^2 |\Sigma(\xi)^{-1}|_{i,j} \right\} \]
\[ - \sum_{j=1}^{N} |\Sigma(\xi_n)\Sigma(\xi)^{-1}|_{j,j} - \text{tr} (\Sigma(\xi_n)\Sigma(\xi)^{-1}) \quad (31) \]

and, in the same way,

\[ E_{x \sim \mathcal{N}} \left\{ \chi^H \Sigma(\xi_n) \chi \right\} = NT. \quad (32) \]

Thus, plugging (31) and (32) into (30) one obtains

\[ \text{KLD} \left( p(x; \xi_n) \| p(x; \xi) \right) \]
\[ = \text{Ln} \frac{|\Sigma|}{|\Sigma(\xi_n)|} + \text{tr} (\Sigma(\xi_n)\Sigma(\xi)^{-1}) + NT. \quad (33) \]

Secondly, one has:

\[ [\Psi]_{n,m} \]
\[ = \frac{|\Sigma(\xi_m)|}{\pi^{N/2} |\Sigma(\xi_m)| |\Sigma(\xi_n)|} \]
\[ \times \int_{\mathbb{C}^N} \exp \left( -\chi^H (\Sigma(\xi_m)^{-1} + \Sigma(\xi_n)^{-1} - \Sigma(\xi)^{-1}) \chi \right) \, dx \]
\[ \times s^{NT} \left[ |\Sigma(\xi_m)|^{-1} + |\Sigma(\xi_n)|^{-1} - |\Sigma(\xi)|^{-1} \right]^{-1} \]
\[ = \frac{|\Sigma(\xi_m)|}{|\Sigma(\xi_n)| |\Sigma(\xi_m)|^{-1} + |\Sigma(\xi_n)|^{-1} - |\Sigma(\xi)|^{-1}}. \quad (34) \]

Consequently, using the fact that

\[ \frac{\partial |\Sigma(\xi)|}{\partial \xi} = \text{tr} \left\{ \Sigma(\xi)^{-1} \frac{\partial \Sigma(\xi)}{\partial \xi} \right\} \]

and plugging (29), (33) and (34) into (24), (23), (22) and (17) one obtains \( C^{\text{MLE}}_{\text{MHI}}, C^{\text{MLE}}_{\text{MCH}}, C^{\text{MLE}}_{\text{MHB}} \), and \( C^{\text{MLE}}_{\text{TBB}}, C^{\text{MLE}}_{\text{TBH}} \), respectively. See Appendix A for non-matrix expressions of \( C^{\text{MLE}}_{\text{TBB}} \) (i.e., in the case \( P = 1 \)).

IV. NUMERICAL SIMULATIONS

The scenario used in these simulations is a ULA of \( N = 5 \) sensors spaced by \( d = \frac{\lambda}{2} \). The noise is assumed to be a complex circular white Gaussian random process with zero-mean and known variance \( \sigma^2 \), uncorrelated both temporally and spatially.

To compare the threshold prediction accuracy we plot the MSE w.r.t. \( \omega \) and \( \phi \) using 1000 Monte Carlo trials. In both deterministic and stochastic cases (see Figs. 1–4), we compute \( C^{\text{MLE}}_{\text{MHI}}, C^{\text{MLE}}_{\text{MCH}}, C^{\text{MLE}}_{\text{MHB}}, C^{\text{MLE}}_{\text{TBB}}, C^{\text{MLE}}_{\text{TBH}} \) using \( L = 2^{10} \) test points (more precisely, we used \( L_1 = 2^7 \) test points over the parameter \( \omega \) and \( L_2 = 2^9 \) test points over the parameter \( \phi \).)

The TTB, \( C^{\text{MLE}}_{\text{TBB}} \), is obtained using \( L = 2^{13} \) test points and also by numerical maximization over \( 2^{12} \) frequency test bins for \( P = 1 \).

A. Threshold Prediction

Figs. 1–4 provide an illustration of the usefulness of the aforementioned deterministic lower bounds in the case of deterministic and sto-
Fig. 4. Lower bounds on the mean square error (the stochastic case) w.r.t. \( \phi \) for near field source localization, with \( T = 100 \) and \( [\theta, r] = [3u, 6\lambda] \).

Stochastic model assumptions for \( \omega \) and \( \phi \). First, one can notice that the MSE of \( \phi \) is lower than the MSE of \( \omega \) which is expected due to the range of those parameters and from the fact that \( \phi \) is the coefficient of the second order, whereas, \( \omega \) is the coefficient of the first order w.r.t. the time delay (see (5)). Second, one can notice that all the aforementioned bounds provide a good prediction of the MSE threshold.

In Figs. 1–4, we considered only one frequency test bin. In this case we notice that the MHB is more accurate than the TTB. This degradation is due to the fact that the TTB is based on lossy compression of the samples of the likelihood ratio function into \( P = 1 \) frequency test-bin (i.e., it considers only one constraints for \( P = 1 \)), whereas the MHB does not apply this lossy compression and use all the information contained in the \( I \) samples in the parameter space (i.e., \( I \) constraints).

Nevertheless, one can note that the advantage of the TTB is its computational cost (the computational complexity of the TTB is lower in comparison to the MSB, HCRB and MHB due to the inversion matrix, see (24), (23), (22) and (17).) Consequently, we can consider the maximization of the TTB over more than one frequency test bins. As shown in the following, this leads to a considerable improvement of the TTB.

B. Effect of the Number of Frequency Test-Bins on the TTB

Considering the maximization over more than only one frequency test bins is essential to ascertain the proper use of the TTB. For \( P > 1 \) one can maximize the TTB via different numerical optimization methods. One of the commonly used approach is to consider a few fast one-dimensional search procedures. More precisely we use a numerical maximization approach under which the frequency test bins \( \Omega_1, \ldots, \Omega_P \) are selected in a sequential manner. In the first step, maximization is performed w.r.t. one test-bin \( \Omega_1 \). In the \( k \)-th step (\( k \leq P \)) maximization is performed w.r.t. \( \Omega_k \) while \( \Omega_1, \ldots, \Omega_{k-1} \) are fixed. This sequential procedure is being continued until \( k = P \).

As shown in Fig. 5, one can notice that this maximization, with respect to the frequency test-bins, leads to a considerable improvement of the threshold prediction (the threshold prediction is now only 2 dB far from the true value, instead of 8–10 dB without maximization). On the other hand, the TTB out performs the MHB (and consequently also the MSB and the HCRB) with a maximization of only \( P = 5 \) frequency test-bins, or more, as illustrated in Fig. 5.

C. Effect of the Number of Sensors on the Threshold

Fig. 6 shows us that the number of sensors has an important effect on the asymptotic variance of the MLE but also on the presence of outliers (which is deduced by the SNR value of the breakdown point).

In this example, a decreasing of 5 sensors increases the SNR value of the breakdown point by approximately 2 dB (i.e., outliers will appear 2 dB earlier if we remove 5 sensors).

D. Effect of the Number of Snapshots on the Threshold

Finally, one should note that increasing the number of snapshots has a similar effect to decrease the noise variance or to increase the SNR as shown in Fig. 7. This can be also explained for the particular case of fixed and constant amplitude, i.e., \( x(t) \sim \mathcal{CN}(a, \Sigma) \), \( t = 1 \ldots T \). In this case, a sufficient statistic is to sum all the observations w.r.t. the snapshots. Since the amplitude is constant, thus, one obtains the following sufficient statistic \( \chi = \frac{1}{T} \sum_{t=1}^{T} x(t) \sim \mathcal{CN}(a, \frac{\Sigma}{T}) \), which is equivalent to reduce the variance by a coefficient equal to the number of snapshots.

V. CONCLUSION

In this paper, we present the derivation of different deterministic lower bounds on the MSE in a near field source localization context. This analysis allowed us to characterize the non-asymptotic performance estimators mean square error. In particular, we focused on the threshold/breakdown prediction. Furthermore, this study shows that the recently proposed TTB out performs its predecessors as the MHB by using only a few one-dimensional sequential maximization over frequency test-bins.
APPENDIX A

In this appendix, we give non-matrix expression of the TTB for the case $P = 1$. In this case, the matrix $W$ will be reduced to a row vector of dimension $L$, such that $[W]_m = \exp(-j2\pi \frac{m-n}{L})$, $m = 1, \ldots, L$. Let $\rho = WW^H$, consequently, one has:

$$\rho = \sum_{m=1}^L \sum_{n=1}^L [R_m] \exp\{2j\pi \frac{n-m}{L}\}.$$  

On the other hand, using (21), one obtains:

$$[R_m] = [W]_m - 2 \sum_{p=1}^2 \sum_{q=1}^2 \left( \frac{\partial \text{KLD} \{p(x; \xi_m) \| p(x; \xi_q)\}}{\partial \xi_p} \right) =: \xi_t.$$

Consequently, one obtains the closed-form expression

$$[C_{\text{TTB}}]_{p,q} = [C_{\text{CHR}}]_{p,q} + \frac{1}{\rho} \sum_{m=1}^L \sum_{n=1}^L \beta(p, m) \beta(q, n) \exp\{2j\pi \frac{n-m}{L}\},$$

where

$$\beta(p, m) = \sum_{q=1}^2 \left( \frac{\partial \text{KLD} \{p(x; \xi_m) \| p(x; \xi_q)\}}{\partial \xi_q} \right) \xi_t,$$
