Abstract—In this paper, we study the security of two recently proposed privacy-preserving biometric authentication protocols that employ packed somewhat homomorphic encryption schemes based on ideal lattices and ring-LWE, respectively. These two schemes have the same structure and have distributed architecture consisting of three entities: a client server, a computation server, and an authentication server. We present a simple attack consisting of three entities: a client server, a computation server, and an authentication server. After a brief discussion of possible countermeasures in Section 3, we analyse the security of these two privacy-preserving biometric authentication protocols that they proposed. Let us start by introducing the notations used.

When $p$ is a prime number, the finite field with $p$ elements is denoted by $\mathbb{F}_p$. For two distinct positive integers $z$ and $d$ with $d < z$, $z \mod d$ is denoted by $[z]_d$ when the operation maps the integers to the interval $[-d/2, d/2]$. Throughout this paper, we let $n = 2^i$, for a positive integer $i$. Then, $R := \mathbb{Z}[x]/(x^n + 1)$ is a ring. Finally, $N \leq n$ denotes the bit-length of a biometric template.

Let us now briefly review the packed SHE schemes proposed by Yasuda et al. in [13], [14] based on ideal lattices and ring-LWE.

A. The SHE scheme based on ideal lattices

Here, we briefly describe the key parameters of a SHE scheme based on ideal lattices and how encryption and decryption are performed. For further details on these, we urge the reader to consult [13], [15], [16].

Key Generation - KeyGen(1^\ell): Upon an input $1^\ell$, where $\ell$ is a security parameter, the key generation algorithm KeyGen outputs a public key $pk = (d, r, n, s)$ and a secret key $sk = \omega \mod \gcd(d, s) = 1$. We note that $n$ is the lattice dimensions, and that $\gcd(d, s) = 1$ and $r^n \equiv -1 \mod d$.

Encryption - $E(m, pk)$: A message $m \in \mathbb{Z}/s\mathbb{Z}$ is encrypted with the public key $pk$ by first choosing a random noise vector $u = (u_0, u_1, \ldots, u_{n-1})$ with $u_i \in \{0, \pm 1\}$ chosen as 0 with probability $q$ and as $\pm 1$ with probability $(1 - q)/2$, and then by computing $ct := E(m, pk) = \left[m + s \sum_{i=0}^{n-1} u_i r^i\right]_d$.

Decryption - $D(ct, sk)$: The message $m$ is recovered from the ciphertext $ct = E(m, pk)$ by computing $[ct \cdot \omega]_d \mod s$.

Let $A = (A_0, A_1, \ldots, A_{N-1})$ be a binary vector of length $N$. Yasuda et al. [13] proposed the following two packing methods.

- PACKING METHOD TYPE 1: Let $F_1 : A \mapsto \sum_{i=0}^{n-1} A_i x^i \in \mathbb{Z}[x]/(x^n + 1)$. Then the type 1 packed ciphertext of $A$ is defined by the integer:

$$vE_1(A) := [F_1(A)(r) + su_1(r)]_d = \left[ \sum_{i=0}^{n-1} A_i r^i + su_1(r) \right]_d.$$
where \((d, r, n, s)\) is the public key \(pk\) and \(u_1(x) \in R\) denotes a noise polynomial.

- **Packing Method Type 2:**
  Let \(F_2 : A \mapsto -\sum_{i=0}^{n-1} A_i x^{n-i} \in \mathbb{Z}[x]/(x^n + 1)\). Then the type 2 packed ciphertext of \(A\) is defined by the integer:
  \[
  \nu E_2(A) := [F_2(A)(r) + su_2(r)]_d = \left[ -\sum_{i=0}^{n-1} A_i s^{n-i} + su_2(r) \right]_d,
  \]
  where \((d, r, n, s)\) is the public key \(pk\) and \(u_2(x) \in R\) denotes a noise polynomial.

### B. The SHE scheme based on ring-LWE

Let \(p\) be a prime number with \(p \equiv 1 \text{ mod } 2n\), and let \(t < p\) be a positive integer. Let the ring \(R_t := \mathbb{Z}_t[x]/(x^n + 1)\) be the plaintext space, and the ring \(R_p := R/pR = \mathbb{F}_p/(x^n + 1)\) the ciphertext space. A SHE scheme based on ring-LWE comprises of the following:

- **Key Generation - KeyGen(\(1^\ell\)):** Upon an input \(1^t\), where \(\ell\) is a security parameter, the key generation algorithm chooses \(s \leftarrow R\) according to a discrete Gaussian error distribution \(\chi := D_g(\sigma)\) with standard deviation \(\sigma\), samples a random element \(a_1 \in R_p\) and an error \(e \leftarrow R\). It outputs \(\text{pk} = (a_0, a_1)\) with \(a_0 := (a_1 \cdot s + t \cdot e)\) and \(\text{sk} = s\) as the public and secret keys, respectively.

- **Encryption - \(E(m, \text{pk})\):** A message \(m \in R_t\) is encrypted with the public key \(pk\) by first sampling \(u, f \leftarrow R\) and then computing \(\text{ct} := E(m, \text{pk}) = (c_0, c_1) = (a_0 u + tg + m, a_1 u + tf) \in R_p^2\).

- **Decryption - \(D(\text{ct}, \text{sk})\):** The message \(m\) is recovered from the ciphertext \(\text{ct} = (c_0, c_1)\) by computing \([c_0 + c_1 s]_p \mod t \in R_t\). In general, from a ciphertext \(\text{ct} = (c_0, \ldots, c_8)\), the corresponding plaintext \(m\) is recovered by computing \(\sum_{i=0}^{8} c_i s^i \mod t\).

Let \(A = (A_0, A_1, \ldots, A_{n-1})\) be a vector of length \(n\) as before. Yasuda et al. [14] proposed the following two packing methods:

- **Packing Method Type 1:**
  Set \(pm_1(A) := \sum_{i=0}^{n-1} A_i x^i\). For sufficiently large \(t\), \(pm_1(A)\) can be considered as an element of \(R_t\). Then define
  \[
  \nu E_1(A) := E(pm_1(A), \text{pk})
  \]
as the type 1 packed ciphertext.

- **Packing Method Type 2:**
  Set \(pm_2(A) := -\sum_{i=0}^{n-1} A_i x^{n-i}\). Again, for sufficiently large \(t\), \(pm_2(A)\) can be considered as an element of \(R_t\). Then define
  \[
  \nu E_2(A) := E(pm_2(A), \text{pk})
  \]
as the type 2 packed ciphertext.

### C. Secure Hamming distance computation

Let \(A = (A_0, A_1, \ldots, A_n)\) and \(B = (B_0, B_1, \ldots, B_n)\) two binary vectors of length \(n\). Then, the Hamming distance between them is
\[
\text{HD}(A, B) = \sum_{i=0}^{n-1} A_i \oplus B_i = \sum_{i=0}^{n-1} (A_i + B_i - 2A_i B_i).
\]
So using the two packed SHE schemes presented above, the Hamming distance is securely computed as follows.

- **Using the ideal lattice based packed SHE:**
  Let
  \[
  C_1 = \left[ \sum_{i=0}^{n-1} x^i \right]_d\quad \text{and}\quad C_2 = [-C_1 + 2]_d.
  \]
  Then, we can securely compute the Hamming distance between \(A\) and \(B\) from their packed encryptions of type 1 and 2, respectively. In particular,
  \[
  \text{ct}_H := \nu E_1(A) C_2 + \nu E_2(B) C_1 + (2\nu E_1(A) \nu E_2(B)),
  \]
  is an encryption of \(\text{HD}(A, B)\) [13].

- **Using the ring-LWE based packed SHE:**
  Let
  \[
  C_1 = -\sum_{i=0}^{n-1} x^{n-i}\quad \text{and}\quad C_2 = \sum_{i=0}^{n-1} x_i.
  \]
  Then, we can securely compute the Hamming distance between \(A\) and \(B\) from their packed encryptions of type 1 and 2, respectively. In particular,
  \[
  \text{ct}_H := \nu E_1(A) C_1 + \nu E_2(B) C_2 + (2\nu E_1(A) \nu E_2(B)),
  \]
  is an encryption of \(\text{HD}(A, B)\) [14].

We note that in both SHE schemes, \(\nu E_1(A) \nu E_2(B)\) corresponds to the encryption of the inner product of \(A\) and \(B\). Namely, the decryption of \(\nu E_1(A) \nu E_2(B)\) results in the inner product of \(A\) and \(B\) [13], [14].

### D. The protocols

Using the two packed SHE schemes presented in the previous section, Yasuda et al. proposed two biometric authentication protocols respectively in [13], [14]. The protocols employ a distributed model for internal entities, which consist of three entities: a client server \(CS\), a computation server \(CS\), and an authentication server \(AS\). Below, we give a description of the protocols, see also Fig. 1. In the description, \(\nu E_1\) and \(\nu E_2\) refer to the respective packed encryption of type 1 and type 2 in the above presented two packed SHE schemes.

- **Setup Phase:** The authentication server \(AS\) generates the public key \(pk\) and the secret key \(sk\) for the SHE schemes, and distributes only \(pk\) to both the client server \(CS\) and the computation server \(CS\), while keeping \(sk\) secret.

- **Enrollment Phase:** The client server \(CS\) generates a feature vector \(A\) from the client’s biometric data (e.g., fingerprints), encrypts \(A\) into a packed ciphertext \(\text{ct}_1(A) = \nu E_1(A)\) of the first type, and sends only \(\text{ct}_1(A)\) with client’s ID to the computation server \(CS\), who then stores \(\text{ct}_1\) and ID in DB.

- **Authentication Phase:** The client server \(CS\) generates a feature vector \(B\) from the client’s biometric data, encrypts \(B\) into a packed ciphertext \(\text{ct}_2(B) = \nu E_2(B)\) of the second type, and sends \(\text{ct}_2(B)\) with the client’s ID to the computation server \(CS\). \(CS\) then retrieves the template \(\text{ct}_1(A)\) corresponding to ID from DB, computes the Hamming distance from \(\text{ct}_1(A)\) and \(\text{ct}_2(B)\), following
Below, we analyse the security of the Yasuda et al. [13, 14] protocols against the other threats. Let us briefly discuss what each entity already knows and what can be done if the entity is malicious.

- **The client server**: $C$ knows $B$ as well as the identity $ID$ of a user, and communicates with the computation server $CS$. He can simulate $CS$. Using $B$, he can find the stored biometric template $A$ by mounting an attack known as the **center search attack** [17] (see Algorithm 2 below). In this attack, the adversary iteratively changes the fresh biometric template until it is rejected. Then, by changing the new template that is just rejected bit-by-bit, he can recover all bits of the stored template. We must mention here that in [14] Yasuda et al. state without giving any proof that their scheme is secure against hill climbing attacks, because all data is encrypted. Unfortunately, this is not true. As we have briefly explained here, the center search attack, which is a type of hill climbing attack, is possible in both protocols. In fact, this attack is possible regardless of the type of employed encryption scheme, as long as the Hamming distance is used to measure the closeness of a fresh biometric template to the reference template.

- **The computation server** $CS$: $CS$ knows the $ID$ of a user and has access to the database $DB$, where the encrypted reference biometric templates are stored. He communicates with the authentication server $AS$. $CS$ can simulate the client server $C$. If he is malicious then his goal could be to recover the stored/fresh biometric templates corresponding to a user $ID$. If $CS$ has access to a fresh biometric template corresponding to an $ID$, then he also can employ the above mentioned center search attack to find out the corresponding stored template. However, as we will show below, there is a simple yet powerful attack that can be employed by $CS$ to recover both the stored and fresh biometric templates of arbitrary users.

- **The authentication server**: $AS$: $AS$ has the secret key. If $AS$ is compromised, the protocol’s security and privacy are also compromised. A malicious authentication server $AS$ can indeed intercept the communication from $C$ to $CS$, and recover the user $ID$ and the biometric templates.

### III. THE ATTACK

In this section, we present an attack algorithm that can be used by the (malicious) computation server $CS$ to recover the biometric templates of arbitrary users. Before we proceed, let us first discuss our threat model.

#### A. Threat model

In [17], Simoens et al. presented a framework for analysing security and privacy of biometric data in biometric authentication systems. Here, we follow their model and consider malicious (or active) internal adversaries. A malicious internal adversary $A$ may deviate from the protocol specifications and may attempt to recover protected information, as long as such attempts are not discovered by the other protocol participants. In a biometric authentication protocol, the relevant protocol entities may pose the following threats to privacy:

- **Biometric reference privacy**: The adversary $A$ should not be able to recover the stored reference biometric template.

- **Biometric sample privacy**: The adversary $A$ should not be able to recover the fresh biometric sample.

- **Unlinkability**: The adversary $A$ should not be able to link a biometric template to the user identity $ID$.

- **Intractability or user indistinguishability**: For a biometric authentication system to be privacy-preserving, the relevant entities must not be able to distinguish whether two authentication attempts are from the same user.

In the protocols under study, the protocol entities know who is trying to authenticate himself to the system. Therefore, from the intractability point of view, both protocols are not privacy-preserving.
chosen bitstring of the same length as $A$, and sends the result to $\mathcal{AS}$, instead of sending the actual correct $ct_H$. For instance, first $\mathcal{CS}$ chooses a bitstring $D$ consisting of $\tau$ consecutive 1’s followed by all 0’s, and computes $vE_2(D)$. Then, he computes $vE_1(A)vE_2(D)$, which corresponds to an encryption of the inner product of $A$ with $D$, and sends the result to $\mathcal{AS}$. If it gets accepted (i.e., $\mathcal{AS}$ outputs YES), then $\mathcal{CS}$ learns that $\sum_{i = 1}^{\tau} A_i \leq \tau$ and in the next round, he flips the $\tau + 1$-th bit of $D$ and sends $vE_1(A)vE_2(D)$ to $\mathcal{AS}$. If it gets accepted, then $\mathcal{CS}$ flips the $\tau + 2$-th bit of $D$ and sends $vE_1(A)vE_2(D)$. This continues until $\mathcal{AS}$ responds NO. (This is the first loop of Algorithm 1). In this way, $\mathcal{CS}$ will recover a portion of $A$ that has Hamming weight $\tau$, and then bit-by-bit he can recover all bits of $A$; see the second and the third loops of Algorithm 1. In the decryption of Algorithm 1, the notation $\beta_i$, for $\beta \in \{0, 1\}$, means that the $i$-th bit is $\beta$.

Algorithm 1 The attack algorithm

Input: $vE_1(A)$ (an encrypted reference template)  
Output: $A = A_1, \cdots, A_N$ (reference template)  
Initialise: $A = 0_10_2 \cdots 0_N$  
For $i = 0$ to $N - \tau$:  
Set $D = 1_1 \cdots 1_{\tau + i}0_{\tau + i + 1} \cdots 0_N$  
Compute $vE_2(D)$  
Send $ct = vE_1(A)vE_2(D)$ to $\mathcal{AS}$  
If rejected Then  
break  
If $i = N$ Then  
Return centerSearch($A$)  
Set $i' = \tau + i$  
Set $A_i' = 1$  
For $i = 1$ to $i' - 1$:  
Set $D = 1_1 \cdots 1_{i - 1}0_{i + 1}1_{i + 2} \cdots 0_{i + 1}0_{i + 2} \cdots 0_N$  
Compute $vE_2(D)$  
Send $vE_1(A)vE_2(D)$ to $\mathcal{AS}$  
If accepted Then  
$A_i = 1$  
For $i = i' + 1$ to $N$:  
Set $D = 1_1 \cdots 1_{i - 1}0_{i + 1}0_{i + 2} \cdots 0_{i + 1}1_{i + 2} \cdots 0_N$  
Compute $vE_2(D)$  
Send $vE_1(A)vE_2(D)$ to $\mathcal{AS}$  
If rejected Then  
$A_i = 1$  
Return $A$

By employing this algorithm, the malicious $\mathcal{CS}$ gains full knowledge of $A$ in at most $2N - \tau$ trials, which can be seen as the sum of the total number of iterations in the three loops of the algorithm. We observe that if the first loop ends without being rejected, then this means that the reference template itself has a Hamming weight less than or equal to $\tau$ and thus, the adversary can mount the center search attack [17] using a bitstring of all zeros. That is why we have centerSearch($A$) as a subroutine in the algorithm. In Algorithm 2, we describe the algorithm for the center search attack.

By using the same algorithm with $vE_2(B)$ as an input and by changing $vE_2(D)$ to $vE_1(D)$ in the algorithm, $\mathcal{CS}$ can recover the fresh biometric template $B$ of any user.

Algorithm 2 The center search attack

Input: $B = B_1, \cdots, B_N$ (a fresh but matching template)  
Output: $A = A_1, \cdots, A_N$ (reference template)  
For $i = 1$ to $N$:  
Set $D = B_1, \cdots, B_i, B_{i + 1}, \cdots, B_N$  
Send $vE_2(D)$ to $\mathcal{CS}$  
If rejected Then  
break  
For $i = 1$ to $N$:  
Send $vE_2(D_1, \cdots, D_i, D_{i + 1}, \cdots, D_N)$ to $\mathcal{CS}$  
If accepted Then  
$A_i = B_i$  
Else  
$A_i = B_i$  
Return $A$

As we can see, the attack is rather simple and straightforward, but powerful. Yasuda et al. [13], [14] claim that as long as $\mathcal{AS}$ manages the secret key $sk$ (for the respective SHE schemes) properly, their protocols would be secure, without any threat model or proof. However, our attack is possible even if $sk$ is securely managed, since $\mathcal{CS}$ can deviate from the protocol specifications without being detected. More specifically, instead of performing the computation (that is, (1) or (2)) that would result in the correct $ct_H$ (a ciphertext encrypting the Hamming distance between the fresh and the stored templates), $\mathcal{CS}$ can replace it with a different ciphertext encrypting a inner product of the target biometric template with a carefully chosen fake template. This new ciphertext allows $\mathcal{CS}$ to gain knowledge of the biometric template using $\mathcal{AS}$’s output. By repeating this procedure at most $2N - \tau$ times (or in at most $2N - \tau$ authentication attempts), $\mathcal{CS}$ can gain full knowledge of a biometric template. Note that in the attack $\mathcal{CS}$ only computes one encryption (of the fake template) and one homomorphic product, so the attack complexity is low.

It may seem obvious that $\mathcal{AS}$ might easily detect this attack due to the structure of the consecutive inputs. However, detecting such inputs is not always feasible if the attacker alternates between malicious and valid authentication attempts. Moreover, the structure in the inputs (to $\mathcal{AS}$) may be masked.

IV. COUNTERMEASURES

As mentioned earlier, the user ID is not protected in Yasuda et al. protocols, and this is not a desirable property from intractability point of view. Hence, we propose a slight modification to the protocols, so that during the enrolment $C$ maps ID to an index and provides it along with the encrypted reference template to $\mathcal{CS}$ for storage. In the authentication phase, $C$ provides a fresh encrypted template and a (possibly) encrypted query to be used by $\mathcal{CS}$ to privately retrieve the reference template from its database. In other words, a private
information retrieval (PIR) [18], [19] technique is employed to retrieve the stored biometric template, and the client server \( C \) provides the PIR query. The rest of the protocols could remain the same, see Fig. 2. In this case, \( CS \) can still employ the PIR query. The rest of the protocols could provide the PIR technique is employed in our attack to recover the templates, but he does not know to whom the templates belong.

In order to prevent the presented attack, we need something more than this. Intuitively, it is obvious that we need a (cryptographic) solution that allows \( AS \) to verify that \( CS \) performed the computations honestly. To be precise, if \( AS \) could check that the input (\( ct_H \)) he received from \( CS \) is the correct ciphertext resulting from equation (1) (or (2)), then the presented attack could be prevented. Since, in this case, \( AS \) would detect the suspicious input provided by \( CS \). However, such verifications may not be possible without introducing some new primitives to the protocol. Indeed, there are cryptographic schemes that allow delegation of computation in a verifiable manner so that the client can verify the correctness of some computations done by a cloud server [20]–[23]. Incorporating such schemes for verifiable delegation of computation seems to be a promising direction for improving the Yasuda et al. protocols. Furthermore, schemes for signatures of correct computation such as the one proposed by Papamanthou et al. [24] would also enable us to combat the described attack. Below we describe a modification to the Yasuda et al. protocols using the Papamanthou et al. [24] scheme for signatures of correct computation.

Signatures of correct computation (SCC) for a function family \( F \) consists of the following four algorithms (KeyGen, Setup, Com, VRFY) [24]. The key generation algorithm KeyGen takes a security parameter and a function family \( F \) as input, and outputs a public/secret key pair \( (PK, SK) \). The setup algorithm Setup takes the secret key \( SK \), the public key \( PK \) and a function \( f \in F \) as input, and outputs the function public key \( FK(f) \) for the function \( f \). These two algorithms are run by a trusted party. In our case, the authentication server \( AS \) can run these algorithms, since \( AS \) is regarded as the trusted party who manages the keys for the SHE schemes. The computation algorithm Com takes the public key \( PK \), a function \( f \in F \) and a value \( \omega \in \text{domain}(f) \) as input, and outputs a pair \((\omega, \sigma)\), where \( \omega = f(\nu) \) and \( \sigma \) is a signature. The verification algorithm VRFY takes the public key \( PK \), the function public key \( FK(f) \) for the function \( f \), a value \( \nu \in \text{domain}(f) \), a claimed result \( \omega \) and a signature \( \sigma \) as input, and outputs 1 if \( \omega \) is correct, otherwise outputs 0.

We note that in [24], there is an algorithm Update that is used to update the function public key for a new function. We omit it here, because in the Yasuda et al. protocols, the function to be computed does not change.

Hence, one way to employ signatures of correct computation in the Yasuda et al. protocols would be requiring \( CS \) to send his computation result \( ct_H \) with a signature back to \( C \), instead of sending \( ct_H \) to \( AS \). Then, \( C \) would verify the correctness of \( ct_H \), and if the verification succeeds, he would send \( ct_H \) to \( AS \); otherwise, \( C \) would abort the protocol. However, in order to guarantee that this shall work, the inputs to the function computed by \( CS \) should be provided by the client server \( C \), that is, both \( vE_1(A) \) and \( vE_2(B) \) must be provided to the computation server \( CS \) by \( C \). However, in the Yasuda et al. protocols, \( vE_1(A) \) is stored on the computation server’s side. We should note here, that the database \( DB \) is controlled by the computation server \( CS \). Therefore, we propose to split the database \( DB \) and the computation server \( CS \) and consider them as two separate entities. With this change, we can have the following modifications to the original Yasuda et al. protocols.

- **Setup Phase:** As in the original protocols, the authentication server \( AS \) generates the public key \( PK \) and the secret key \( SK \) for the SHE schemes, and distributes only \( PK \) to the client server \( C \) and the computation server \( CS \). \( AS \) also generates the public/secret \((PK, SK)\) for the SCC scheme and the function public key \( FK(f) \) for the function \( f \) (running the algorithms KeyGen and Setup), which takes two inputs and is defined as in (1) (and/or (2)). He then distributes \((PK, FK(f))\) to \( C \) and \( PK \) to \( CS \).

- **Enrollment Phase:** The client server \( C \) generates a feature vector \( A \) from the client’s biometric data, encrypts \( A \) into a packed ciphertext \( ct_1(A) = vE_1(A) \) of the first type and maps \( ID \) to an index \( i, 1 \leq i \leq N \), and sends only \( ct_1(A) \) with \( i \) to the database \( DB \) for storage. See Fig. 3(a).

- **Authentication Phase:**
  - **Phase 1 - Communication** \( C \rightarrow DB \): The client server \( C \) takes the client ID and extracts the corresponding index \( i \). Then, \( C \) privately retrieves the reference template \( ct_1(A) = vE_1(A) \) corresponding to the index \( i \) from the database \( DB \). See Fig. 3(b) for a schematic description.
  - **Phase 2 - Communication** \( C \rightarrow CS \): The client server \( C \) generates a feature vector \( B \) from the client’s biometric data, encrypts \( B \) into a packed ciphertext \( ct_2 = vE_2(B) \) of the second type, and sends \( ct_1(A) \) and \( ct_2(B) \) to the computation server \( CS \). Upon receiving \( ct_1(A) \) and \( ct_2(B) \), \( CS \) runs the computation algorithm \( Com(PK, f, ct_1(A), ct_2(B)) \), and returns the output, which is \( CT_H \) and a signature \( \sigma \), to \( C \).
  - **Phase 3 - Communication** \( C \rightarrow AS \): The client server \( C \) first checks the correctness

---

of $ct_H$, by running the verification algorithm $\text{VRFY}(PK, FK(f), ct_1(A), ct_2(B), ct_H, \sigma)$. If the verification algorithm outputs 1, then $C$ forwards $ct_H$ to the authentication server $AS$, otherwise, he aborts the protocol. The authentication server $AS$ decrypts $ct_H$ with the secret key $sk$ to obtain the Hamming distance $HD(A, B)$. Finally, $AS$ returns the authentication result YES (resp. NO) to $C$ if $HD(A, B) \leq \tau$ (resp., otherwise).

Fig. 3: Schematics of a proposed modification to the Yasuda et al. biometric authentication protocols.

V. CONCLUSIONS AND FUTURE WORK

In this paper, two recently proposed privacy-preserving biometric authentication protocols that employ packed somewhat homomorphic encryption (SHE) based on ideal lattices and ring-LWE are reviewed. We presented a simple yet powerful attack that enables a malicious computation server to gain full knowledge of the stored and the fresh biometric templates of arbitrary users. The attack takes advantage of an homomorphic property of the employed encryption scheme, namely, the secure inner product computation. Another key factor that allows the attack to be launched undetected is the lack of a verification that the computation server performed the correct computation.

Furthermore, we discussed possible countermeasures. As a quick fix, we first proposed the use of private information retrieval in order to avoid storing the user ID in the database. This way, one can reduce the impact of the attack, since the adversary will not be able to link the recovered biometric template to a user identity. In order to prevent the attack, we discussed how a scheme for signatures of correct computation may offer secure solutions to the problem. In particular, we proposed to separate the database from the computation server in order to incorporate the scheme for signatures of correct computation, and changed the flow of information between the protocol entities. We would like to further investigate these areas in the future, and improve the protocol to achieve provable security and full privacy. For now, it is safe to say that SHE alone is not enough to build a fully privacy-preserving biometric authentication protocol. Great care must be taken when designing such a protocol based solely on SHE.
