Received: September 12, 2007; In Final Form: November 2, 2007

Nitrogen-doped titanium dioxide (TiO₂/N) nanoparticle thin films have been produced by a sol−gel method with hexamethylenetetramine (HMT) as the dopant source. The synthesized TiO₂/N thin films have been sensitized with CdSe quantum dots (QDs) via a linking molecule, thioglycolic acid (TGA). Optical, morphological, structural, and photocurrent properties of the thin films with and without QD sensitization have been characterized by AFM, TEM, XPS, Raman spectroscopy, UV−visible spectroscopy, and photocurrent techniques. AFM measurements reveals that films with thicknesses of 150 and 1100 nm can be readily prepared, with an average TiO₂ particle size of 100 nm. TEM shows a uniform size distribution of CdSe QDs utilized in sensitizing the TiO₂/N films. Doping of the TiO₂ crystal lattice by HMT was confirmed to be 0.6−0.8% by XPS. Differences in crystal phase caused by the precursors HMT, nitric acid, and poly(ethylene glycol) (PEG) are elucidated using XRD and Raman spectroscopy. The resultant crystal phase of TiO₂/N varies but is a mixture of anatase, brookite, and rutile phases. UV−visible absorption spectra show that N doping of TiO₂ causes a red-shifted absorption into the visible region, with an onset around 600 nm. Nitrogen doping is also responsible for the enhanced photocurrent response of the TiO₂/N nanoparticle films in the visible region relative to undoped TiO₂ films. In addition, CdSe QDs linked to TiO₂/N nanoparticles using TGA were found to significantly increase the photocurrent and power conversion of the films compared to standard TiO₂/N films without QD sensitization. The incident photon-to-current conversion efficiency (IPCE) is 6% at 400 nm for TiO₂/N−TGA−CdSe solid-state solar cells and 95% for TiO₂/N−TGA−CdSe films near 300 nm in a Na₂S electrolyte, which is much higher than that of undoped TiO₂ with QD sensitization or TiO₂/N without QD sensitization. The power conversion efficiency (η) was found to be 0.84% with a fill factor (FF%) of 27.7% with 1100 nm thick TiO₂/N−TGA−CdSe thin films. The results show that combining nitrogen doping with the QD sensitization of TiO₂/N thin films is an effective and promising way to enhance the photoresponse in the near-UV and visible region, which is important for potential photovoltaic (PV) and photoelectrochemical applications.

1. Introduction

In recent years, there is an increasing interest to find sustainable alternative energy (SAE) sources due to the heightening cost of fossil fuels and the detrimental effects of global climate change. Photovoltaic (PV) cells have received significant attention due to the limitless influx of photons from the sun. Recent market energy analysis is predicting energy parity between conventional energy production and PV costs in cents per kilowatt hour (cents/kW h) in only 5−8 years. Silicon solar cells have attained a solar conversion efficiency of 20%; however, the manufacturing process is very expensive and involves the use of toxic chemicals inherent in the semiconductor industry.

To date, there have been reports of two types of solar cells based on nanostructured semiconductor materials, the Grätzel solar cell, based on dye-sensitized nanoporous semiconductor thin films, and the quantum dot solar cell, based on composite films of semiconductor nanoparticles (CdSe) and conjugated polymers studied by Greenham et al. Grätzel’s initial report in 1991 presented a nanocrystalline dye-sensitized solar cell converting light to electrical energy with an efficiency of 7%. The dye-sensitized solar cell (DSSC) consists of TiO₂ nanoparticles acting as a highly porous, wide band gap semiconductor, electron acceptor layer. In the DSSC, visible-light-absorbing dye molecules adsorbed onto the TiO₂ surface act as the sensitizer to harvest more of the solar flux. Under irradiation, the photoexcited dye molecules inject electrons into the TiO₂ layer that are transported through the porous TiO₂ layer and collected by a conductive fluorine-doped SnO₂ layer on the glass surface. The oxidized dye is regenerated by a liquid electrolyte, with the highest reported efficiency of about 10%. Greenham investigated the processes of charge separation and transport in the interface between a conjugated polymer and semiconductor nanocrystal as a hybrid organic−inorganic system. A quantum efficiency of up 12% has been reported with a high
concentration of nanocrystals, where both nanocrystals and polymers provide continuous pathways to the electrodes. The absorption, charge separation, and transport properties of the composites were found to be a function of the size, material, and the surface ligands of the nanocrystals utilized.

TiO₂ and ZnO nanoparticles represent good examples of nanocrystalline materials used for potentially low-cost PV devices for energy conversion as an alternative to silicon solar cell technology and for photocatalysis. Titanium dioxide (TiO₂), or titania, exists in three crystalline phases, anatase, rutile, and brookite. Anatase and rutile have found uses mainly in PV cells, photoelectrochemical cells (PEC), and photocatalysis applications. On the contrary, the brookite phase has not received similar attention, perhaps because it is the most difficult to prepare in the form of a thin film. Titania has a wide band gap (3.2 eV) and absorbs only 5% of the solar spectrum, resulting in poor conversion efficiency in solar cell applications. Nonmetal-doped TiO₂ nanoparticles and nanotubes have been shown to produce electronic states in the TiO₂ band gap, thereby extending photoresponse to the visible region and improving photoactivity. Recent studies of TiO₂/N and ZnO/N have found success in narrowing the band gap and increasing light harvesting efficiency with nitrogen doping, and further investigations have been focusing on the resulting photoelectrochemical properties and photocatalytic activity for SAE production. Several different synthesis protocols have been developed to produce TiO₂/N. The usual doping process involves using ammonia as a nitrogen source by sol–gel, thermal, or hydrothermal chemical methods.

An alternative method to obtain TiO₂/N involves using HMT by chemical and mechanochemical processes. The resulting effect on crystalline phase composition showed increased photocatalytic activity and photovoltaic properties, with specific morphologies produced. Nitrogen doping within TiO₂ can be interstitial or substitutional, with the latter being more effective, resulting in mixing of N 2p states with O 2p states and contributing to the band gap narrowing. Different techniques have been used to study N-doped TiO₂ crystallographically, including XPS, EPR, Raman spectroscopy, XRD, and absorption spectroscopy. Theoretical studies have supported the visible absorption and the resulting yellowish color of TiO₂/N thin films and powders.

Alternative techniques to increase the photoresponse besides doping include the utilization of tunable narrow band gap semiconductor nanoparticles or quantum dots (QDs) such as CdS, CdSe, and CdTe to sensitize wide band gap semiconductor such as the metal oxides, for example, TiO₂ and ZnO. QDs with their large extinction coefficient strongly absorb visible light, inject electrons into the conduction band of metal oxides, and thereby, contribute to increased solar energy conversion. Attachment of CdSe QDs to nanocrystalline TiO₂ has been shown to be successful with an immersion method using a bimolecular linker. Sonochemical, photodeposition, and chemical bath deposition of CdSe on TiO₂ nanoparticles and nanotubes has also been studied for photocatalysis applications. However, the use of QDs to improve TiO₂-based solar cell efficiency is still an area of active exploration.

In this work, we demonstrate a relatively simple approach to dope TiO₂ nanoparticles with nitrogen and also efficiently sensitize the doped nanoparticles with CdSe QDs. The nanoparticle films have been characterized in terms of their structural, optical, and morphological properties using a combination of experimental techniques. The results show substantially enhanced photoresponse and improved conversion efficiency of the TiO₂ nanoparticle films when nitrogen doping and QD sensitization are used in unison. Possible explanations are provided in terms of the morphological and optical properties of the films. This method based on combined doping and QD sensitization is promising for solid-state PV cells and photoelectrochemical applications.

2. Experimental Section

2.1. Sample Preparation. Materials. Titanium(IV) isopropanoxide (97%, technical-grade trietylphosphine (TOP-#117854, 90%), triethylphosphine oxide (TOPO-#223301, 99%), potassium chloride (KCl-#204099, 99%), poly(ethylene glycol) (PEG-#25322–68–3, average M₅₀ of ca. 10000 g/mol), and sodium sulfide (Na₂S-#407410, 99%) were obtained from Sigma-Aldrich (Milwaukee, WI). Cadmium oxide (CdO-#223791000, 99%) and selenium powder (Se 200 mesh-#198070500, 99%) were obtained from Acrros Organics (Morris Plains, NJ). 1-Tetradecylphosphonic acid (TDPA-#4671–75–4, 99%) was obtained from PCI synthesis (Newburyport, MA). Nitric acid (2.0 N-#LC178502) was purchased from Lab. Chem Inc. (Pittsburgh, PA). Thioglycolic acid (TGA-#103036, 98%) was obtained from MP Biomedicals Inc. (Solon, OH). F/SnO₂ conductive glass (Tec glass 30 Ohms) was obtained from Hartford glass (Hartford City, IN), and the Ag/AgCl reference electrodes were from CH Instruments Inc. (Austin, TX).

TiO₂ Film Preparation. Four kinds of TiO₂ films (TiO₂-1, TiO₂-2, TiO₂-3, and TiO₂-4) were made by a sol–gel method. All TiO₂ films were made using 375 μL of titanium isopropanoxide as a precursor, which was stored in a nitrogen-filled glovebox. For TiO₂-1, TiO₂-2, TiO₂-3, and TiO₂-4, titanium isopropanoxide was injected into 250 μL of Milli-Q water and 5 mL of ethanol within the glovebox. TiO₂-1 solutions did not contain nitric acid, while TiO₂-2 solutions contained a dropwise addition of nitric acid until the solution reached a pH ~ 1.23. TiO₂-3 solutions are similar to TiO₂-2, but 0.05 g of HMT was added under vigorous stirring. Solution TiO₂-4 is similar to TiO₂-3, with an addition of 0.90 g of poly(ethylene glycol) (PEG-10,000 g/mol) under vigorous stirring, all within an O₂-free environment. As a point of clarification, acidification (TiO₂-2, TiO₂-3, and TiO₂-4) was performed outside of the glovebox prior to titanium isopropanoxide addition within the glovebox. The sol was then stirred for 3 days within the glovebox at ambient temperatures (~25 °C). All TiO₂ films were made by spin coating at 2000 rpm for 60 s onto FTO (SnO₂/F) conducting substrates in ambient conditions. The thickness was estimated with the mass, area, and density of the TiO₂ films and was confirmed with AFM measurements (~150 and ~1100 nm thick). The films were annealed at 550 °C for 1.5 h with a Leister heat gun in open air conditions. For thin TiO₂-1, TiO₂-2, TiO₂-3, and TiO₂-4 films, 50, 200, 100, and 50 μL of the sol solution was used, respectively. For thick TiO₂-1, TiO₂-2, TiO₂-3, and TiO₂-4 films, 400, 200, 700, and 250 μL, respectively, of the sol solution was used. The sol solution was put on the conductive glass with 2.2 cm² areas. It was necessary to apply different volumes in order to obtain approximately the same film thickness because of the different viscosities of the various solutions.

CdSe QD Synthesis. High-quality CdSe QDs were synthesized based upon the protocol of Peng et al., wherein CdO is utilized as the Cd precursor and TDPA and TOPO are the ligands and coordinating solvents, respectively. The resulting CdSe nanocrystals were in the strong confinement size regime and were synthesized in normal air-free reaction conditions. The synthesis of the CdSe nanoparticle follows the procedure reported by Robel et al., wherein 0.05 g (~0.39 mmol) of CdO, 0.3 g (~1.1
mmol) of TDPA, and 4 g of TOPO were heated to 110 °C and degassed under vacuum and then heated to 300 °C under a nitrogen flow (Schlenk line). A SeTOP (0.7% by weight) solution was obtained by adding 0.026 g of Se powder with 4.25 mL of TOP inside of a glovebox and stirring for 1 h to ensure complete dissolution of the Se powder. After reaching 300 °C, the Cd–TDPA–TOPO solution was cooled to 270 °C prior to the injection of SeTOP. Under a nitrogen flow, 3 mL of SeTOP was injected, which resulted in the lowering of the temperature to 260 °C. The temperature was then increased to 280 °C to facilitate particle growth, and aliquots were removed and probed to track nanocrystallite growth via UV–vis absorption spectroscopy and photoluminescence (PL) spectroscopy. The CdSe solution was cooled and was removed from the reaction flask at around 80 °C and dissolved into ~10 mL of toluene. The QDs in toluene were then cleaned twice through a precipitation and decantation regime using methanol and toluene. The QDs in toluene were then cleaned twice through a precipitation and decantation regime using methanol and centrifugation at 3000 rpm, and the QDs were ultimately redissolved in toluene prior to their use as a sensitizer.

CdSe QD Linkage to TiO₂. CdSe QDs were linked to nanocrystalline TiO₂ and TiO₂/N thin films using TGA as a molecular linker. TiO₂ has a strong affinity for the carboxylate group of the linker molecules, while the sulfur atom of TGA binds strongly to CdSe nanoparticles through surface Cd²⁺ cations. The films were dried with a heat gun at 100 °C for 4 h to remove H₂O from the surface due to ambient humidity adsorption. They were later immersed in undiluted neat TGA for 12 h in a nitrogen environment in a glovebox. The films were then immersed in toluene, removing the excess TGA, and in turn immersed in a CdSe solution for 12 h inside of the glovebox. Four films of 2.2 cm² were immersed in 5 mL of CdSe QDs suspended in toluene, as described earlier. The TiO₂/N–TGA–CdSe films were stored in a nitrogen-filled glovebox and not exposed to light prior to PEC characterization. The solid-state TiO₂/N–TGA–CdSe cell after PEC measurements remained stable for months. The TiO₂/N–TGA–CdSe cell in the electrolyte is very stable; however, when it is removed from the Na₂S electrolyte and are in ambient conditions, the thin films’ properties deteriorate after experimentation. Long-term stability needs to be further studied in future research.

2.2. Structural and Morphological Characterization. X-ray photoelectron spectroscopy (XPS) studies of the films were carried out on an X-ray photoelectron spectrometer (XPS, PHI Quantera SXM) using a non-monochromatized Al KR X-ray source (1486.6 eV). The energy resolution of the spectrometer was set at 0.5 eV. The binding energy was calibrated using a C 1s (284.6 eV) spectrum of a hydrocarbon that remained in the XPS analysis chamber as a calibration tool. Crystalline phase identification was performed via X-ray diffraction (XRD) in conjunction with Raman spectroscopy. XRD analysis was conducted on a MINIFLEX diffractometer operating at 30 kV/15 mA using Cu–Kα radiation and a scanning speed of 1°/20/min.

Raman spectroscopy of the films was performed using a Renishaw micro-Raman setup with a (5/10/20/50)× objective lens and a 633 nm wavelength laser (Research Electro-Optics, Inc., Boulder, CO). Renishaw’s WiRE (Windows-based Raman environment) was used for collection and data analysis of 1–5 scans ranging in accumulations of 1–10 s.

AFM images of the films without and with QDs were acquired under ambient conditions with a PicoLE SPm instrument (Molecular Imaging) in tapping mode. The tapping mode cantilevers exhibit resonant frequencies between 60 and 90 kHz (typical 75 kHz), force constants of 2.5–5.5 N/m, and tip apex radii of ~10 nm. The resulting images were flattened and plane-fit using software from Molecular Imaging. Silica-etched tips were purchased from MikroMasch (Watsonville, OR).

A JEOL model JEM-1200EX microscope was used for the low-resolution transmission electron microscope (TEM) studies of the CdSe QDs. The TEM was equipped with a Gatan Model 792 Bioscan digital camera running on a Windows 2000 computer with the Gatan Digital micrograph as the analyzing software.

2.3. Optical and Electrochemical Characterization. UV–vis absorption spectroscopy was conducted on a Hewlett-Packard 8452A diode array spectrophotometer. UV–vis absorption spectra were measured first by placing a blank FTO glass substrate in the light path, subtracting the absorption pattern, and then performing the UV–vis absorption measurement on the collection of TiO₂ thin films.

Photoluminescence (PL) spectroscopy was gathered on a Perkin-Elmer LS 50B with an excitation wavelength of 390 nm and a 1% attenuator. QDs in toluene were placed in an opened 1 cm path length quartz cuvette for both UV–vis absorption and PL measurements. Thin films were placed in a thin film sample holder from Perkin-Elmer (#52123130) for PL spectra.

Photoelectrochemical studies (linear sweep voltammetry and incident photon-to-current conversion efficiency (IPCE)) in the solid state and in an electrolyte were carried out with a CHI440 electrochemical workstation (Austin, TX). Linear sweep voltammetry was used to obtain the I–V profiles. Actively investigated thin films were the TiO₂, TiO₂/N, and TiO₂/N–CdSe thin films described earlier. A Ag/AgCl and Pt wire coil were used as the reference and counter electrodes, respectively. Before each measurement, the Na₂S electrolyte solution was deaerated by bubbling ultrahigh-purity N₂ for 20 min through the electrolyte solution, and a nitrogen flow was also subsequently blown over the surface during data gathering. For I–V measurements, a halogen lamp was utilized (75 W), and for IPCE measurements, a 1000W Xe lamp (Oriel Research arc lamp assembly #69924 and power supply #69920) coupled to an infrared (IR) water-filled filter (Oriel # 6127) was used and then aligned into a monochromator (Oriel Cornerstone 130 1/8m) for spectral resolution from 300 to 800 nm. An aqueous Na₂S solution served as the redox couple to maintain the stability of the QDs, as discussed elsewhere. A Maximum photocurrent was produced with 1 M Na₂S using 6.5 mL of Milli-Q water (18 MΩ). Diminished molarities of Na₂S were found to decrease the overall photocurrent performance. IPCE measurements were also conducted for solid-state TiO₂/N–TGA–CdSe solar cells. A schematic of the photoelectrochemical setup is shown in Figure 1a,b.

3. Results

The amount of nitrogen in N-doped TiO₂ nanoparticle films was identified by the XPS technique. Figure 2 shows the XPS spectra for the TiO₂–3 film. Figure 2a shows the Ti 2p, O 1s, C 1s, N 1s, and Sn binding energies from 0 to 1000 eV (Sn is identified from the conductive film). Figure 2b shows only the nitrogen binding energy from 396 to 408 eV, showing two peaks at 400 and above 401.2 eV. To compare the effect of HMT and PEG, the TiO₂–3 film has 37.45% of O and 11.27% of Ti. The TiO₂–4 film shows elemental compositions of C and N of 39.93 and 0.80%, respectively, with 48% of O and 11.27% of Ti.

Figure 3 shows the XRD patterns for all of the films prepared for determining the crystal phases of both TiO₂ and TiO₂/N.
All of the XRD data show the crystal phase of the conductive glass (SnO₂/F), which is marked as SnF. The TiO₂-1 film (without nitric acid) XRD pattern is representative of the anatase crystal phase (Figure 3a). For the TiO₂-2 film (with nitric acid), the brookite and rutile phases appear, with a mix of anatase, brookite, and rutile phases (Figure 3b). With HMT added for the TiO₂-3 film, a mixture of brookite and rutile phases dominates, with a trace amount of the anatase phase (Figure 3c). With further addition of PEG and HMT, as in the TiO₂-4 film, the brookite and rutile phases decrease, and the anatase is predominant. Additional evidence for the various crystal phases of the different films comes from their Raman spectra that show anatase as the primary phase for TiO₂-1 and TiO₂-4 (Figure 4a and c) and a mix of anatase, brookite, and rutile phases in TiO₂-2 and TiO₂-3 films. Representative Raman spectrum of the TiO₂-3 film is shown in Figure 4b. It can be seen that the characteristic peak for the anatase phase at 144 cm⁻¹ shifts slightly to 146 cm⁻¹ with nitrogen doping (TiO₂-3 and TiO₂-4 films).

The morphology of the films with and without QDs was studied by AFM in ambient conditions. The average TiO₂ nanocrystal size was found to be around 100 nm in diameter. Films with HMT (TiO₂-3) or HMT plus PEG (TiO₂-4) show more porosity than TiO₂-1 and TiO₂-2 films. A representative AFM image for the TiO₂-3 film with about 150 nm thickness is shown in Figure 5a. For thicker films (e.g., 1100 nm), TiO₂ particles were observed to form clusters. All films showed the presence of CdSe QDs after they were sensitized, as exemplified by the AFM image for the TiO₂-3—CdSe film shown in Figure 5b. While it is not easy to determine the exact size of the CdSe QDs based on AFM, the average size of the QDs appear to be on the order of a few nanometers. To better characterize the CdSe QDs, TEM measurements were conducted. Figure 6 shows a representative TEM image of CdSe QDs. The image appears to show reasonably uniform size distributions of the CdSe QDs, with an average diameter of 3.5 nm.

Optical absorption of the different films was characterized by UV−vis spectroscopy, with emphasis on comparing the effect of nitrogen doping through HMT or nitric acid. Figure 7 shows a comparison of the UV−vis absorption spectra of different films. For films without HMT and PEG (TiO₂-1 and TiO₂-2), the absorption is primarily around 340 and 400 nm (Figure 7a and b). However, for films with HMT (TiO₂-3 and TiO₂-4), the spectra show an obvious red shift of the absorption edge toward the visible region, with peaks around 350, 426, and 542 nm (Figure 7c) or 412 and 532 nm and an absorption onset at 600 nm (Figure 7d). Figure 7e shows the UV−vis absorption spectrum of the TiO₂-3—CdSe film, with strong absorption around 560 nm due to the CdSe QDs. For comparison, Figure 8a and b shows the absorption and photoluminescence (PL) spectra of CdSe QDs in toluene under ambient conditions. The absorption spectrum shows the expected strong and sharp excitonic peak around 560 nm, while the PL spectrum shows a
narrow emission band near 580 nm, which is clearly due to band edge emission. Figure 8c shows the PL spectrum of the TiO$_2$-3-TGA-CdSe film, with a relatively weak emission peak at 575.5 nm, which is slightly blue-shifted with respect to the PL peak of CdSe QDs in toluene solution.

The current–voltage (I–V) profiles for solar cells fabricated using films with different thicknesses (150 and 1100 nm) were obtained using a halogen lamp and 1 M Na$_2$S. With the cell configuration shown schematically in Figure 1, the I–V profiles measured are shown in Figure 9. The cell without HMT (TiO$_2$-1–CdSe film) presents a low short-circuit current density of $-1.169 \mu A/cm^2$ with an open-circuit voltage of $-1.3 V$ (Figure 9a) within the voltage window of $-1.4 V$, and the fill factor is 14.8% with a low power conversion efficiency of $\eta = 0.120\%$. For the cell based on the TiO$_2$-3-TGA-CdSe thin film (150 nm), the I–V curve in Figure 9b shows a short-circuit current ($-242 \mu A/cm^2$) with an open-circuit voltage of $-1.0 V$, a fill factor of 25.4%, and a power efficiency of $\eta = 0.228\%$. The cell based on the TiO$_2$-3-TGA-CdSe thick film (1100 nm) has the highest short-circuit ($-683 \mu A/cm^2$) with an open-circuit voltage of $-1.2 V$, and the highest fill factor of 27.7% and a power conversion efficiency of $\eta = 0.840\%$. The short-circuit current and open-circuit voltage found in Figure 9 are summarized in Table 1.

The fill factor (FF) and power conversion efficiency ($\eta\%$) were calculated using the short-circuit current and open-circuit voltage$^{45}$ and are also given in Table 1

$$FF = \frac{j_{V_{\text{max}}}}{j_{sc} V_{oc}}$$

$$\eta = \frac{j_{V_{\text{max}}} V_{oc}}{I_{i}} = \text{FF}(j_{sc} V_{oc}) I_{i}$$

Figure 2. (a) XPS spectra of a nitrogen-doped TiO$_2$-3 film on a SnO$_2$/F substrate showing C, N, Ti, O, and Sn spectra peaks. (b) A detailed N 1s XPS band.

Figure 3. XRD patterns of TiO$_2$ films on the SnO$_2$/F substrate prepared by the sol–gel method, using different chemicals in the TiO$_2$ synthesis, annealed at 550 °C for 1.5 h with a heat gun for (a) a TiO$_2$-1 film (without nitric acid), (b) a TiO$_2$-2 film (using nitric acid), (c) a TiO$_2$-3 film (using nitric acid and HMT), and (d) TiO$_2$-4 (using nitric acid, HMT, and PEG). The phases found in the films are anatase, rutile, and brookite, marked by A, R, and B, respectively. SnF represents the crystal phase of the conductive glass (SnO$_2$/F).

Figure 4. TiO$_2$ film Raman spectra of (a) TiO$_2$-1 (without nitric acid, HMT, or PEG), (b) TiO$_2$-3 (using nitric acid and HMT in the synthesis), and (c) TiO$_2$-4 (using nitric acid, HMT, and PEG in the synthesis).

The incident photon-to-current conversion efficiency (IPCE) was studied for solid cells and in an electrolyte (1M Na$_2$S) with different thicknesses. The IPCE at different wavelengths was determined from the short-circuit photocurrent ($j_{sc}$), where $V = 0$ at different excitation wavelengths ($\lambda$) using the expression

$$\text{IPCE\%} = \frac{[(1240 \times j_{sc} (A/cm^2))/(\lambda (nm) \times I_{i} (w/cm^2))] \times 100}{1}$$

where $I_{i}$ is the incident light power. The IPCE results of TiO$_2$...
and TiO\(_2\)/N without and with CdSe QDs are shown in Figure 10. It is clear that the photocurrent response is much stronger with the presence of CdSe QD sensitization. The TiO\(_2\)-1-TGA-CdSe film (QD-sensitized but without N doping) shows photocurrent responses at 300, 530, and 620 nm, with the highest response near 300 nm with IPCE = 56%. The TiO\(_2\)-3-TGA-CdSe film (QD-sensitized and N-doped) shows a similar response but an overall stronger IPCE with the highest response around 95% at 300 nm. The IPCEs of both films closely match the absorption spectrum of CdSe QDs and TiO\(_2\)/N, as shown in Figure 7e. The IPCE% is 1.06 at 300 nm for TiO\(_2\)/N (magnified 10× in Figure 10), showing photocurrent responses at 320, 360, and 420 nm, which are also close to the absorption spectrum as shown in Figure 7c.

In addition, the IPCE% of TiO\(_2\)-3-TGA-CdSe thin film (150 nm) solid cell was studied, and the result is shown in Figure 11. It can be seen that peaks at 480 and 600 nm correspond to absorption of the CdSe QDs (see Figure 11 inset that shows the absorption and emission spectra of the CdSe nanoparticles in toluene). This cell shows an IPCE response around 6% at 400 nm, and the results are summarized in Table 2.

**Figure 5.** AFM images of (left) a nitrogen-doped TiO\(_2\)-3 thin film (175 nm) and (right) N-doped TiO\(_2\)-3 nanoparticles linked to TGA-CdSe nanoparticles (film thickness ~ 1100 nm).

**Figure 6.** Representative TEM image of CdSe quantum dots showing an average particle size around 3.5 nm.

**Figure 7.** UV–vis absorption spectra of the films (a) TiO\(_2\)-1 (without nitric acid), (b) TiO\(_2\)-2 (using nitric acid in the synthesis without HMT), (c) TiO\(_2\)-3 (synthesized with nitric acid and HMT), (d) TiO\(_2\)-4 (synthesized with HMT and PEG), and (e) TiO\(_2\)-3–TGA–CdSe. The blank was the substrate of SnO\(_2\)/F (of the conductive glass).

**4. Discussion**

4.1. N Doping of TiO\(_2\) Nanoparticles with HMT. It is known that HMT hydrolyzes in aqueous solutions to form...
Figure 8. UV–vis absorption spectra of (a) CdSe nanoparticles and (b) photoluminescence (PL) spectra of CdSe nanoparticles in toluene excited at 390 nm. (c) Photoluminescence of a TiO$_2$-3 film doped with nitrogen and sensitized with CdSe QDs.

Figure 9. I–V characteristic of (a) a TiO$_2$-1–TGA–CdSe thick film, (b) a TiO$_2$-3–TGA–CdSe thin film, and (c) a TiO$_2$-3–TGA–CdSe thick film using 1 M Na$_2$S, excited with a halogen lamp with an incident light intensity of $I_l = 27$ mW/cm$^2$.

Ammonia and formaldehyde above 70 °C, as shown in the following equation

$$C_6H_{12}N_4 + 6H_2O \xrightarrow{\text{Hydrolysis}} 6HCO + 4NH_3$$  (4)

Ammonia reacts with TiOCH(CH$_3$)$_2$ (TTIP) to form a nitrogen-containing precursor (TiO$_2$$-x$N$_y$·nH$_2$O). Dehydration of the TiO$_2$ complex in pure and doped TiO$_2$ samples is completed at temperatures below 200 °C, and NH$_3$ molecules remain until the calcination temperature rises to 300 °C. Therefore, crystallization of TiO$_2$$-x$N$_y$ can be summarized as

$$\text{TiO}_2(\text{TTIP}) + H_2O, \text{NH}_3, \text{etc.} \rightarrow \text{TiO}_2$$\text{-x}N$_y$+nH$_2$O $\xrightarrow{300^\circ C}$ TiO$_2$-xN$_y$  (5)

A yellowish tint was observed in all films synthesized with HMT or HMT plus PEG, suggesting the presence of a TiO$_2$/N sol–gel solution. The XPS spectra for all of the films showed two evident peaks corresponding to Ti 2p and O 1s at 458.5 and 531.5 eV binding energies, accompanied by traces of Sn from a conductive SnO$_2$/F film over which the TiO$_2$ films were formed. Also, traces of carbon at 284 eV were also present due to the intentional hydrocarbon contamination used for calibration. The carbon (C 1s) atom percentage increases from 29% for TiO$_2$-1 to 37% and 40% for TiO$_2$-3 and TiO$_2$-4, respectively. The TiO$_2$-4 prepared with both HMT and PEG contains the highest carbon content, which may be attributed to uncombusted material from the precursor solutions, including HMT and PEG. The sample prepared with PEG, TiO$_2$-4, contains the highest carbon content. Sample TiO$_2$-2 prepared with nitric acid and without HMT in vacuum presents extremely weak nitrogen signals at 401.2 eV. However, TiO$_2$-3 and TiO$_2$-4 films exhibit N 1s at ~400 and 401.2 eV, which are indicative of nitrogen.

incorporation. We attribute N 1s at 400 eV to N atoms from 
N–N, N–H, O–N, or N-containing organic compounds 
as a result of the brookite phase, and peaks at 230, 445, 
and 604 cm
–1, indicative of a rutile phase. The TiO
2 films 
contain a mixture of peaks that can be attributed to 
ananate, brookite, and rutile phases as a result of nitric acid 
corporation. The lowest-frequency mode shifts slightly for these films 
to 146 cm
–1 , as compared to 144 cm
–1 for the pure anatase 
(TiO
2-1). This might be caused by changes in crystallographic composition 
due to nitrogen doping attributed to the vibrations of 
Ti–N–O introduced by nitric acid and HMT. 

Raman spectrum of the TiO
2-4 thin film shows that PEG suppresses 
the formation of the rutile and brookite phases, also consistent 
with XRD data. The intensity of the 146 cm
–1 peak for the 
TiO
2-3 film is higher and sharper than that of undoped TiO
2, 
indicating good crystallinity and size uniformity of the TiO
2/N film.

4.2. Morphological Properties. The composition of the thin 
films was observed to be a mix of individual particles intercon- 
nected with high porosity. However, TiO
2-3 and TiO
2-4 films 
were far more porous than the TiO
2-1 and TiO
2-2 films. This 
suggests that HMT and PEG promote porosity, as was previ- 
ously demonstrated in the case of PEG interacting with TiO
2 systems. 
The morphology was noticeably more evident by 
AFM due to an atomically flatter surface produced with thin 
films on the order of 150 nm in thickness. The surface properties 
of the TiO
2/N films are expected to be important in determining 
how well the CdSe QDs can link to and interact with the TiO
2 
films on the order of 150 nm in thickness. The surface properties 
of the TiO

2 
films

spectra of all samples studied show that films without 
HMT and PEG (TiO
2-1 and TiO
2-2) have absorption around 
340 and 400 nm, respectively. However, TiO
2-3 and TiO
2-4 
films with HMT or HMT plus PEG have a red shift of the 
absorption edge toward the visible region at 600 nm for samples 
annealed at 550 °C due to the electronic transition of CdSe to 
Ti d
0. The red-shift absorption can be 
explained by the doping of nitrogen into the crystal lattice of 
TiO
2 due to the addition of HMT in the sol–gel solutions. 

All of the films sensitized with CdSe QDs exhibit strong absorption at 
560 nm, which is the characteristic excitonic absorption band 
of CdSe QDs (Figure 7e).

As shown in Figure 8, CdSe QDs in solution exhibit strong 
and narrow band edge emission at 580 nm. While the PL 
spectrum of the TiO
2-3–TGA–CdSe film shows a weak and 
blue-shifted PL band peaked at 575.5 nm. These results suggest 
interactions between TiO
2 nanoparticles and CdSe QDs and 
likely electron injection from CdSe to TiO
2. The small blue 
shift of the PL peak could be due to slight oxidation of the film 
exposed to the atmosphere and thus a decrease in CdSe QD 
size during the sensitization process. The electron-transfer 
process indicated by PL quenching is supported by photoelec-
is possibly because the TiO$_2$-1 and TiO$_2$-2 films also have a PL emission at 580 nm due to CdSe QDs. However, there is no blue shift of the PL spectrum. This is possibly because the TiO$_2$-1-CdSe and TiO$_2$-2-CdSe have lower porosity than TiO$_2$-3 and TiO$_2$-4 and the CdSe QDs are not inside the pores of the TiO$_2$ film and thereby have weak interactions with TiO$_2$ nanoparticles. This is illustrated schematically in Figure 1d. The average QD size is estimated to be 3.5 nm based on the absorption spectrum.

4.4. Photoelectrochemical and Photovoltaic Characterization. As summarized in Table 1, thin and thick films sensitized with CdSe QDs show enhanced photocurrents and power conversion efficiency under white light, in comparison to films without sensitization of the CdSe QDs. The greatest enhancement was observed for TiO$_2$ films doped with nitrogen and simultaneously sensitized with CdSe QDs. What is interesting is that the QD-sensitized TiO$_2$/N shows much larger enhancement than that of the simple sum of just N doping and only QD sensitization, especially in terms of photocurrents (Figure 9). One possible explanation is that N doping alters the surface property of the TiO$_2$ film so that the interaction between TiO$_2$ and CdSe QDs becomes stronger and allows for more efficient electron injection. XPS data also revealed a localization of nitrogen upon the surface (Figure 2b), and binding between exposed Cd$^{2+}$ and surface nitrogen atoms on TiO$_2$ could also increase interaction. The porosity of the TiO$_2$ film could also be affected by N doping that, in turn, influences how the CdSe QDs enter the pores and adsorb onto the TiO$_2$/N nanocrystalline surface. The mixed brookite and rutile phases could also have some effect on the CdSe-TiO$_2$ interaction.

For the thick TiO$_2$-1 and TiO$_2$-2 films, it was also observed that a layer of CdSe QD film formed on the TiO$_2$ film surface. This seems to indicate that CdSe QDs did not all disperse into the pores of the TiO$_2$ films efficiently and were instead localized upon the TiO$_2$ surface. Therefore, CdSe QDs inject electrons mainly into the TiO$_2$ film surface, with CdSe QDs in contact with a thin layer of TiO$_2$ nanoparticles, which could possibly explain why the short-circuit current, FF, and conversion efficiency are low for these two films. However, the conversion efficiency of TiO$_2$-2 is higher than that of TiO$_2$-1, probably due to nitrogen residues from the nitric acid added to the TiO$_2$ sol.

In comparison to the thick TiO$_2$-3-TGA-CdSe film with the highest power conversion efficiency ($\eta = 0.84\%$), the TiO$_2$-4-TGA-CdSe (CdSe QD sensitized with HMT and PEG) has a lower conversion efficiency. This could possibly be due to a weakened interaction between CdSe QDs and TiO$_2$ nanoparticles caused by hydrocarbon species on the TiO$_2$ surface from uncombusted poly(ethylene glycol) (PEG). It is clear that IPCE is enhanced when the films are sensitized with CdSe QDs (Table 2) due to their strong visible absorption and electron injection. The highest IPCE percentage was found for TiO$_2$-3-TGA-CdSe films (95% in 300 nm), where the larger content of brookite and rutile phases of the TiO$_2$/N was present. The lower IPCE in TiO$_2$-1 samples is possibly due to the lower porosity and probably due to the presence of the anatase crystalline phase (Figure 10). The performance of the solid solar cell is similar to that reported previously, as shown in Figure 11. In this case, the highest IPCE is 6% at 400 nm and a strong response, larger than 4%, was observed at 600 nm. The first increase at 600 nm is attributed to the absorption onset of the 4.6 nm QDs utilized to sensitize the TiO$_2$-3-TGA-CdSe film. The direct overlap with the first excitonic band (inset figure 11) of the CdSe QDs with the IPCE measurements confirms the electron injection into the TiO$_2$ conductive band. This, in turn, confirms the important role of the QDs to harvest photons and increase the generated photocurrent. All of these results indicate the sensitive dependence of the cell performance on the film porosity, QD-TiO$_2$ interaction, and N doping.

The electronic band structure of the CdSe QD and TiO$_2$/N could help to better understand the reason behind the increased performance in TiO$_2$/N thin films sensitized with CdSe. Figure 12 shows different electron–hole relaxation, recombination...
pathways, and band structures of both CdSe QDs with a band gap of 2.17 eV (3.5 nm in average diameter) and nitrogen-doped TiO2 with an overall band gap of 3.2 eV at pH = 7. The band diagrams of CdSe and TiO2/N have both been placed in relation to the normal hydrogen electrode (NHE). CdSe QDs of 3.5 nm have a top valence band position of ~+0.7 V and a conduction band of approximately ~−1.4 V based on previous reports. The band structure of TiO2/N, in turn, has a valence band at ~+2.6 V and a conductive band at approximately −0.6 V based on the work by Sathivel and Kisch. N doping introduces a state at 1.14 eV above the valence band and 2.06 eV (600 nm absorption onset) below the conduction band of TiO2. Several groups have also reported an absorption onset at 600 nm via reflectance spectroscopy. Incorporation of nitrogen into nanocrystalline TiO2 acts as an electron acceptor site within the TiO2 band gap and effectively should be considered as a p-type doping. This state acts as an electron acceptor site within the TiO2 band gap. Now, it is still important to consider the typical n-type behavior of TiO2 as a result of oxygen vacancies in the crystal lattice, which therefore act as donor sites within the structure and effectively increase the Fermi level (EF) to more negative potentials (versus NHE). The band gap dopant N state is populated, as evidenced by the weak absorption onset at 600 nm (2.06 eV) explained by Asahi et al. as a N 2pΠ to Ti dσ transition. Due to the relatively weak absorption of this N 2pΠ to Ti dσ electronic transition in comparison to the quantum-confined CdSe transition (1S1S to 1S1S), we expect that, for the CdSe QD-sensitized TiO2/N films, the optical absorption is dominated by the CdSe QDs.

To understand the charge-transfer and recombination kinetics, we will ignore the weak absorption due to N doping for the QD-sensitized TiO2/N film. In this case, photoexcitation of the CdSe QD generates a hole in its valence band and an electron in its conduction band. The electron in the conduction band of the CdSe QD is injected into the conduction band of TiO2 (left to right black arrow (D)), and the transfer of the hole in the valence band of CdSe can be mediated by the electron-occupied N state (right to left black arrow (E)). The energy level of the N state is close to the top of the valence band of CdSe, and this proximity in energy will aid in the hole (or electron)-transfer process. Since this only exists for the CdSe QD-sensitized and N-doped TiO2 film, the N-mediated hole transport may be the key to the enhanced photoelectrical response of this film compared to that of TiO2 films with only N doping or only QD sensitization. This is possible, especially considering that the hole transport is often the limiting step for overall charge transport in nanoparticle films.

It is clear that N doping into TiO2 has introduced extra pathways for the charge carriers that could be beneficial for overall charge transport and thereby cell performance. Optimization of the system via an increased dopant level (currently 0.6–0.8%; see Table 1) and manipulation of the capping agents of CdSe may further enhance the photocurrent density as well as power conversion efficiency above that of 0.84%, which is currently observed.

5. Conclusions
Several TiO2 films with nitrogen doping and/or CdSe QD sensitization have been systematically investigated using a combination of synthetic, spectroscopic, XRD, XPS, microscopy, and electrochemistry techniques. The structure of TiO2/N has been found to be generally a mixture of anatase, brookite, and rutile phases. Nitrogen doping into the TiO2 lattice results in a red shift of the electronic absorption and enhanced photocurrent response of relative to undoped TiO2 films. In addition, CdSe QDs linked to TiO2/N nanoparticles were found to significantly increase the photocurrent and power conversion of the films compared to those of standard TiO2/N films without QD sensitization. The IPCE is 6% at 400 nm for TiO2/N–CdSe solid-state solar cells and 95% for TiO2/N–TGA–CdSe films near 300 nm in a Na2S electrolyte, which is much higher than that for undoped TiO2 with QD sensitization or TiO2/N without QD sensitization. A power conversion efficiency (η) of 0.84% was found along with a fill factor (FF%) of 27.7% for 1100 nm thick TiO2/N–TGA–CdSe thin films. The results show that the combination of nitrogen doping and QD sensitization of the TiO2 thin films is an effective way to enhance the photoresponse, which is promising for photovoltaic (PV) and photoelectrochemical applications.
