Abstract: Glycolytic isozymes that are restricted to the male germline are potential targets for the development of reversible, non-hormonal male contraceptives. GAPDHS, the sperm-specific isoform of glyceraldehyde-3-phosphate dehydrogenase, is an essential enzyme for glycolysis making it an attractive target for rational drug design. Toward this goal, we have optimized and validated a high-throughput spectrophotometric assay for GAPDHS in 384-well format. The assay was stable over time and tolerant to DMSO. Whole plate validation experiments yielded Z' values >0.8 indicating a robust assay for HTS. Two compounds were identified and confirmed from a test screen of the Prestwick collection. This assay was used to screen a diverse chemical library and identified fourteen small molecules that modulated the activity of recombinant purified GAPDHS with confirmed IC₅₀ values ranging from 1.8 to 42 μM. These compounds may provide useful scaffolds as molecular tools to probe the role of GAPDHS in sperm motility and long term to develop potent and selective GAPDHS inhibitors leading to novel contraceptive agents.

Keywords: Glycolysis, GAPDHS, high throughput screening, sperm, contraceptive.

INTRODUCTION

Sperm-selective targets are being investigated to develop novel, reversible small molecule contraceptives. These include distinct isozymes in the glycolytic pathway [1-5], such as glyceraldehyde-3-phosphate dehydrogenase S (GAPDHS) [6, 7]. GAPDHS is ~70% identical to its somatic GAPDH isozyme, with amino acid differences distributed along the length of the protein [5, 8, 9]. The most distinctive structural feature of the sperm isozyme is a proline-rich N-terminal region that has no homology to somatic GAPDH enzymes from widely divergent species. Expression of GAPDHS is restricted to the male germline, offering the potential for contraception by selective inhibition of sperm metabolism without blocking glycolysis in other tissues. Gene targeting studies determined that mice lacking GAPDHS are infertile and produce sperm with very low ATP levels and no progressive motility [10]. These studies demonstrate the importance of glycolysis for sperm energy production and also provide evidence that inhibition of GAPDHS should not impair testicular function, since sperm production is unaffected in mice lacking this enzyme [10].

Early studies identified α-chlorohydrin and related derivatives as potential male contraceptives with reversible effects on fertility at low doses (reviewed in [11, 12]). Numerous reports detailed the inhibitory effects of α-chlorohydrin on GAPDHS activity, its ability to impair sperm motility and fertility and its selectivity versus the somatic GAPDH. However, side effects were observed *in vivo* [11-13]. More recently, structure-based drug design approaches have been applied to GAPDHS (from rat) to identify novel leads for male contraceptive development [7]. Few differences were observed between the active sites of human somatic GAPDH and sperm-specific GAPDHS, although differences elsewhere on the protein were noted that might be targetable for selective inhibitors of GAPDHS [7].

Drug targeting of GAPDH enzymes is not restricted to contraceptive studies. Compounds to inhibit pro-apoptotic activity of human GAPDH are also being investigated [14]. GAPDH has also proven to be an attractive drug target in protozoa [15] such as trypanosomes [16] and *Entamoeba* [17], since many of these parasites rely solely on glycolysis for their energy supply. Structure- and catalytic mechanism-based approaches have been applied to design compounds that inhibit the glycolytic enzymes of the parasites without affecting the corresponding proteins of the human host [18-20]. For some trypanosomatid enzymes, potent and selective inhibitors have already been developed that affect only the growth of cultured trypanosomatids, and not mammalian cells [16].

Towards the goal of discovering potent inhibitors for the validation of human GAPDHS as an important and novel

[#]Joint first authors.

target for male contraceptive development, we carried out a high throughput screen (HTS) against purified recombinant human GAPDHS lacking the proline-rich region. An NAD-dependent assay for GAPDHS activity was optimized and validated for HTS. We screened 56,000 compounds selected to maximize chemical diversity. From this collection, we identified 14 hits by dose-response confirmatory testing.

MATERIALS AND METHODOLOGY

Reagents

Unless otherwise stated all reagents were purchased from Thermo Fisher Scientific (Waltham, MA) or Sigma Aldrich (St. Louis, MO) at the highest level of purity possible. Human somatic GAPDH purified from erythrocytes (catalog # G6019) was purchased from Sigma Aldrich and was greater than 90% pure as judged by SDS-PAGE. DL-glyceraldehyde 3-phosphate (GAP) (catalog # G5251) was purchased from Sigma-Aldrich. Costar 384-well, flat-bottom, clear plates were from Corning (Lowell, MA) (catalog # 3702). The Prestwick Chemical Library was obtained from Prestwick Chemical (Washington, DC). The compounds for high throughput screening and IC₅₀ determinations were obtained from Asinex Corporation (Moscow, Russia).

Construction of the Recombinant Human GST-GAPDHS

Unless stated, all procedures were performed according to manufacturer's procedures. The gene for human sperm-specific glyceraldehyde-3-phosphate dehydrogenase (GAPDHS) (Accession No. NM_014364.4) lacking the proline-rich N-terminal region, and comprising residues 69-408, was synthesized (GeneArt Inc., Burlington, CA) with optimal codon usage for bacterial expression. The GAPDHS gene was flanked by an EcoRI and a XhoI site that were used to sub-clone the gene into the prokaryotic GST fusion vector, pGEX-4T-1 (GE Healthcare Life Sciences, Piscataway, NJ). The predicted molecular weight of the GST-GAPDHS construct was calculated as 63,729.39 Da.

Expression and Purification of Hu GST-GAPDHS in *E. coli*

Expression of GST-GAPDHS was performed in the gapA-deficient *E. coli* strain DS112 [21] obtained from the *E. coli* Genetic Stock Center (New Haven, Connecticut) as strain CGSC#7563. For large scale expression and purification, 6L cultures of DS112/GST-GAPDHS were grown at 37°C in M9 minimal media supplemented as described [21] and containing ampicillin and chloramphenicol. The cultures were grown at 37°C to an OD ~0.5, the incubation temperature was reduced to 30°C and the cell culture induced for 48 h with a final concentration of 0.2 mM IPTG. Cells were harvested, resuspended in lysis buffer (DPBS, 1 mM PMSF (MP Biomedicals, Solon, OH), 1 mM EDTA (Promega, Madison, WI), 1 mM DTT (US Biochemicals, Santa Clara, CA), 10 µg/ml lysozyme (Fisher BioReagents, Suwanee, GA), 0.1% Triton X-100) and lysed at 23,000 psi by passage through a M-110EH homogenizer (Microfluidics, Newton, MA). After centrifugation at 30,000g for 1 h, the resulting supernatant was added to pre-equilibrated Glutathione agarose resin (Pierce, Rockford, IL) (6 ml resin/100 ml lysate) and incubated overnight at 4°C. After washing, GST-GAPDHS was eluted with 10 mM glutathione (Thermo Sci-

entific, Rockford, IL) in 50 mM Tris-HCl, pH 8.0. Purified GST-GAPDHS protein was stored at -80°C. Recombinant GST-GAPDHS samples were analyzed by SDS-PAGE (4-12% Bis-Tris gels, NuPAGE MOPS SDS running buffer, Invitrogen) and gels stained with Coomassie blue. Protein concentrations were estimated by Bradford assay (Bio-Rad Laboratories, Hercules, CA). Analytical size exclusion chromatography was carried out on a Superose 12 column (GE Healthcare) as previously described [22].

Enzymatic Assay for GAPDHS

The dehydrogenase activity of GAPDHS was measured kinetically by monitoring the accumulation of NADH at 340 nm [23] immediately following the addition of the substrate, DL-glyceraldehyde-3-phosphate (GAP). One enzyme unit is defined as the amount of enzyme necessary for the formation of 1 µmol of 1,3-diphosphoglycerate min⁻¹. GAPDH was assayed at pH 8.9, optimal for its activity [24]. For K_m determination for GAP, the reaction mixture contained GAPDHS, 50 mM glycine, 50 mM potassium phosphate, pH 8.9, 5 mM EDTA, 0.5 mM NAD and a 14 point GAP concentration range between 0 and 10 mM GAP. Assays were performed at room temperature.

Compound Libraries and Handling

A chemical collection of 56,000 compounds was purchased from Asinex Corp. All compounds in the Asinex library adhere to Lipinski's rule of 5, with no more than 5 hydrogen bond donors, no more than 10 hydrogen bond acceptors, a molecular weight under 500 g/mol, and a partition coefficient (LogP) less than 5 [25]. All compounds are registered in ActivityBase (IDBS Inc., Guildford UK) and can be positionally located in bar-coded 384-well plates with associated SD file data. Compound handling for HTS was essentially as previously described [26, 27]. Compounds are stored at 4°C in 384-well Greiner V-bottom polypropylene plates (catalog # 781280) (Greiner Bio-One, Monroe, NC) in 100% DMSO at 10 mM and 1 mM concentrations. For HTS, 0.5 µL of 1 mM compound in DMSO was spotted into columns 3 - 22 of dry Costar clear flat bottom 384-well assay plates (catalog #3701, Corning Corp., Corning, NY) using a Biomek[®] NX (Beckman Coulter Inc., Fullerton, CA) and P20 tips. Columns 1, 2, 23, and 24 were spotted with 0.5 µL of DMSO for use as positive and negative controls. Dry spotting of compounds into assay plates was performed as a routine method to conserve compounds [26]. For dose-response measurements, 4 µL of the 10 mM DMSO stock of selected compounds was added to 1 µL of DMSO using a Biomek[®] NX.

The Prestwick collection containing 1,120 FDA approved compounds was prepared as 10 mM stocks in 100% DMSO. Compounds (0.5 µL) were pre-spotted into the 384-well plates using a Biomek[®] NX to give a final screening concentration of 10 µM.

High Throughput Screening GAPDHS Assay

The high throughput screening (HTS) assay for GAPDHS is based on the standard spectrophotometric assay of GAPDH activity described above. For HTS, all steps were carried out at room temperature in Costar clear flat-bottom 384-well plates pre-spotted with either 0.5 µL DMSO or 0.5 µL of compound. The assay consisted of two 25 µL addi-

tions carried out using a Thermo Multidrop 384-well liquid dispenser (Thermo Scientific, Waltham, MA). Reactions with inhibitors were carried out with a 15 min preincubation of compounds with 25 μ L of GAPDHS/NAD. The enzymatic reaction was then initiated by addition of 25 μ L of GAP substrate. The final HTS assay (50 μ L) contained 30 nM GAPDHS, 50 mM glycine, 50 mM potassium phosphate, pH 8.9, 5 mM EDTA, 1 mM DTT, 1% DMSO, 0.5 mM NAD and 0.5 mM GAP and a final concentration of 10 μ M compound for single-point screening. For HTS, maximum signal positive controls contained only DMSO (no compound), while the minimum controls were obtained by adding all assay components except enzyme. Kinetic reads (at 30 sec intervals for 5 min) of the plates were carried out on a Spectramax Plus 384 reader (Molecular Devices, Sunnyvale, CA). Inhibition data was analyzed in ActivityBase and using Microsoft Excel. Hits were defined using a standard deviation based-hit threshold (signal mean (μ) plus 3x the standard deviation (σ) in the compound data, $\mu+3\sigma$).

Estimation of Assay Quality

The Z' -factor was used to assess the quality of the assay and estimate the screening window [28]. The Z' -factor incorporates both the dynamic range of the assay and well-to-well variability. Values are obtained by running one whole 384-well plate of maximum (max) signal control and one whole 384-well plate of minimum (min) signal control. Z' -factor was calculated using the formula: $Z' = 1 - (3SD_{\max} + 3SD_{\min}) / (\text{Mean}_{\max} - \text{Mean}_{\min})$

where SD = standard deviation. Max = maximum signal. Min = minimum signal.

Dose Response Measurements

For IC_{50} determinations, serial dilutions of compounds (8 mM stock concentration in DMSO) were performed in 100% DMSO with a two-fold dilution factor resulting in 10 final concentrations spanning 80 μ M to 0.165 μ M. The serially diluted compounds (0.5 μ L) were dry spotted into assay plates and were assembled as described for the single-concentration screen. For each concentration, percent inhibition values were calculated and IC_{50} values and Hill slopes determined using a four-parameter dose-response (variable slope) equation in GraphPad Prism or using XLfit software (IDBS). Some compounds were also tested by dose response in the presence of detergent (0.01% Tween-20 final concentration). In some cases, compounds were also tested by dose response against a form of human histag-GAPDHS expressed in the baculovirus/insect cell system [22]. Buffer conditions were as described above and his-GAPDHS was used at a final concentration of 60 nM in the assay.

Ligand Efficiency Calculation

IC_{50} values were used to calculate ligand efficiency (LE or Δg) and binding efficiency index (BEI) [29]. Ligand efficiency normalizes the binding energy of the ligand ($\Delta G = -RT \ln IC_{50}$) at 300 K ($\sim 27^\circ\text{C}$) to the number of non-hydrogen atoms in the molecule ($\Delta g = \Delta G N_{\text{non-H atoms}}^{-1}$) [30], while BEI expresses binding affinity per total molecular weight (MW) of the inhibitor ($\text{BEI} = -\log IC_{50} \text{ MW}^{-1}$) [29].

Compound Filter Assay

The ability of compounds to interfere with the GAPDHS assay readout was assessed as follows. The enzymatic assay

was run kinetically as described above until an absorbance (A_{340}) of 0.7 was reached. Compounds were then added to the reaction to a final compound concentration of 50 μ M and the A_{340} measured immediately after this addition.

Statistical Analysis

GraphPad Prism 5 (GraphPad Software, San Diego, CA) was used for nonlinear regression statistical analysis. GraphPad InStat Student's two tailed t-test was used for comparing IC_{50} values, differences were considered significant at $p < 0.05$.

RESULTS

Expression of full-length GAPDHS in *E. coli* has proven difficult in quantities sufficient for screening a large number of compounds [7]. Substantially better yields and activities were obtained by elimination of the proline-rich N-terminal region [1] that is not required for enzyme activity [22]. When typical *E. coli* strains were used for expression, mass spectrometry analyses confirmed that mouse GAPDHS and the host bacterial GAPDH formed mixed tetramers, resulting in the co-purification of bacterial and recombinant enzymes (data not shown). A similar observation has been made for the rat GAPDHS expressed in *E. coli* with the purified tetrameric enzyme consisting of 3 subunits of *E. coli* GAPDH and 1 subunit of rat GAPDHS [7]. Our approach was to express recombinant human GAPDHS lacking the proline-rich N-terminal region in a GAPDH-deficient *E. coli* strain (CGSC strain #7563). Further, the form we expressed was a GST-GAPDHS fusion protein to improve solubility. The size and purity of soluble recombinant GST-GAPDHS was confirmed by SDS-PAGE with a band at ~ 60 kDa observed (Fig. 1A). Typical yields were ~ 13 mg of purified GST-GAPDHS per 6L *E. coli* culture. Hu GST-GAPDHS protein purified from *E. coli* was further characterized by analytical size exclusion chromatography as previously described [22]. GST-GAPDHS was applied to a Superose 12 column and eluted as a mixture of three forms (Fig. 1B), with peak 1 eluting in the void volume. Comparison with known protein standards indicated that the elution volumes of peaks 2 and 3 corresponded most closely to the tetrameric and monomeric forms of GST-GAPDHS respectively, with $\sim 75\%$ of the protein estimated as tetrameric, 10% monomeric and the remainder presumably in some aggregated form.

The GST-GAPDHS fusion protein had enzymatic activity, enabling us to avoid substantial losses that occurred during thrombin cleavage to remove the GST protein tag. Consequently, the uncleaved GST-GAPDHS protein was used for all subsequent studies and will be referred to as GAPDHS from here on.

GAPDHS Assay Development and Optimization

GAPDHS activity was measured using a standard spectrophotometric assay monitoring the accumulation of NADH at 340 nm [23] following the addition of the substrate, DL-glyceraldehyde-3-phosphate (GAP). The assay was developed with a final assay volume of 50 μ L in 384-well format. GAPDHS activity was measured kinetically by taking absorbance readings every 30 sec over 5 min. The GAPDHS activity in the assay was directly proportional to the concentration of enzyme (Fig. 2). The K_m values for GAP and NAD

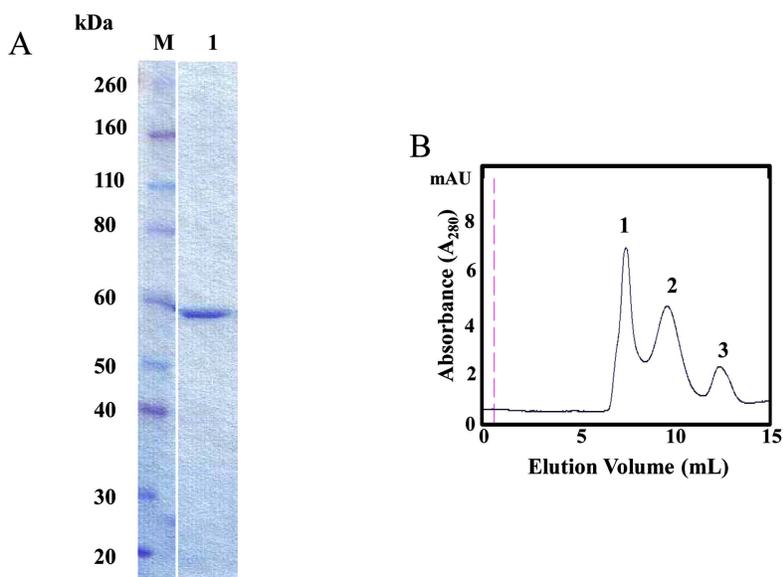

Fig. (1). Characterization of GST-GAPDHS. **(A)** SDS-PAGE analysis of purified recombinant human GST-GAPDHS. GST-GAPDHS was expressed in the *gapA*-deficient *E. coli* strain DS112 and purified using glutathione-Sepharose. Coomassie-Blue stained 4-12% Bis-Tris gel, lane M, Prestained protein markers (Novex); lane 1, recombinant human GST-GAPDHS (2 μ g). **(B)** Size exclusion chromatography of purified GST-GAPDHS. Purified human GST-GAPDHS was loaded on a Superose 12 column at 0.5 ml/min in 50 mM potassium phosphate pH 7.0, 400 mM NaCl buffer. The molecular size of the peaks indicated by the numbers were estimated as described previously [22].

were determined as 1.1 mM (Fig. 3) and 0.1 mM (data not shown), respectively. Activity of the purified recombinant human GAPDHS was \sim 46 U/mg, comparable to the activities of commercial preparations of GAPDH purified from rabbit muscle (Sigma). For HTS, an assay concentration of 30 nM GAPDHS was chosen which provided both an adequate assay window and linear GAPDHS enzyme activity over the time of the assay.

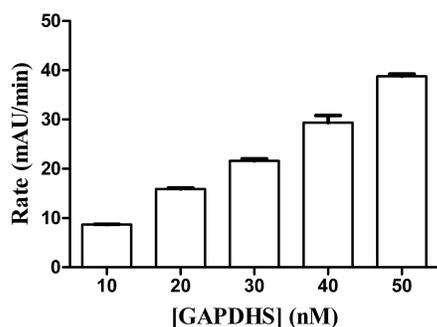

Fig. (2). GAPDHS Enzyme Titration. GAPDHS was titrated at the indicated concentrations under the final assay conditions. Data points represent average of four determinations per concentration.

For our preferred HTS scheme, 0.5 μ L of compound per well is pre-spotted in 384-well plates giving a final compound concentration of 10 μ M in the final 50 μ L assay volume. Because the compounds to be screened are dissolved in DMSO, the DMSO tolerance of the assay was assessed. Concentrations up to 5% DMSO had no effect on GAPDHS activity (Fig. 4). For the HTS and dose response experiments, the maximum concentration of DMSO is 1%. Addition of up to 1% BSA was also tested, but found to have no effect on GAPDHS activity in the assay (data not shown). Substrate concentrations were set at 0.5 mM NAD (5x K_m

NAD) and 0.5 mM GAP (0.5x GAP K_m) with the goal of biasing the screen toward detection of GAP competitive compounds.

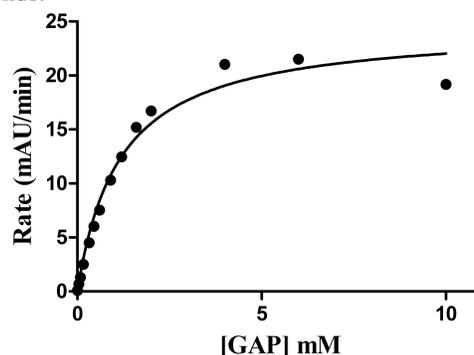

Fig. (3). Determination of the K_m value for GAP substrate. GAP was titrated at a 14 point concentration range between 0 and 10 mM in the assay using 8 nM GAPDHS. K_m value was calculated using non-linear regression analysis for the Michaelis-Menten equation in GraphPad Prism 5.

GAPDHS Assay Automation and Validation

To assess variability of the GAPDHS assay with full automation, triplicate 384-well DMSO plates in a typical “Min-Mid-Max” experiment [28, 31] were analyzed to determine Z' -factor [28] as a measure of assay quality. To facilitate HTS, the assay was simplified into two steps using Multidrop 384 (Thermo Fisher) bulk dispensers (Table 1). The assay was run as a 5 min kinetic read. All plates were pre-spotted with 0.5 μ L DMSO using a Biomek NX liquid handling workstation. Initial experiments were conducted in the absence of compounds to evaluate the robustness of the assay window by measuring statistically significant changes in enzyme rates between no GAPDHS (minimum signal \blacktriangle),

0.5x GAPDHS concentration (mid signal \blacklozenge) and 1x GAPDHS concentration (maximum signal \blacksquare) (Fig. 5A).

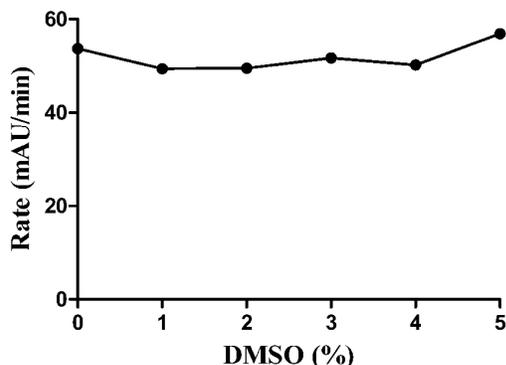

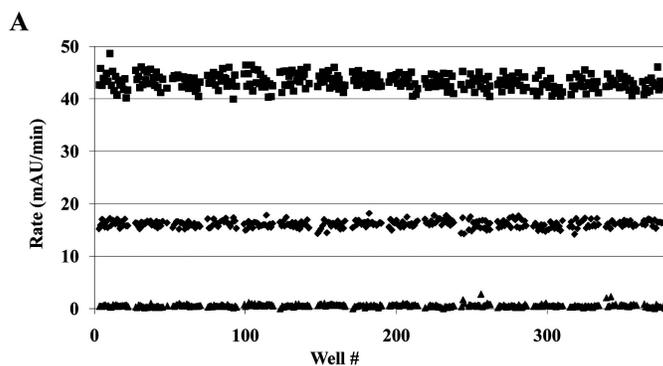

Fig. (4). Tolerance of GAPDHS assay to DMSO. DMSO was tested in the GAPDHS HTS assay (30 nM GAPDHS, 50 mM glycine, 50 mM potassium phosphate, pH 8.9, 5 mM EDTA, 1 mM DTT, 1% DMSO, 0.5 mM NAD and 0.5 mM GAP) at the indicated concentrations of DMSO.

The data yielded a calculated Z' -factor for individual plates of 0.88 and CVs <5% (Fig. 5B) demonstrating a suitable assay window and acceptable variability for HTS as typically defined [28, 31, 32] and [NIH Chemical Genomics Center Assay Guidance Manual: (http://spotlite.nih.gov/assay/index.php/Table_of_Contents)]. For HTS, typically 10-20 compound plates are screened in one run. To assess the stability of the assay over such a ten 384-well plate run, a variability study was performed allowing compound preincubation with GAPDHS and NAD for 15 min or 60 min to simulate the first and tenth plate conditions, respectively. In comparison, the data yielded a calculated Z' for individual plates of 0.83 and CVs of 5.03% for the 60 min preincuba-

tion study demonstrating the robustness of the assay over the time frame required to screen ten 384-well plates. The assay was repeated for a second day with comparable results for Z' and CVs (data not shown). The scheme used for HTS was to add the GAPDHS/NAD solution to the 10 plates at 6 min intervals, to add GAP to each plate after its 15 min compound incubation, and then to read immediately thus ensuring that compound incubation times were identical for all wells on all plates (Table 1).

GAPDHS Pilot Screen

As a final validation, a small test set of diverse compounds was screened to determine the performance of the GAPDHS assay under HTS conditions in the presence of typical small molecule compounds. In this pilot screen, the process and the plates with controls were set-up exactly as for the primary screen. We used the Prestwick collection, a purchased compound library made up of 1,120 compounds with established biological activities, 90% of which are FDA-approved drugs. The Prestwick library was screened at 10 μ M in the automated GAPDHS assay and hits were identified using a standard deviation based hit-threshold [33] (signal mean (μ) plus 3x the standard deviation (σ) in the compound data, $\mu+3\sigma$). The Z' -factors for the controls on each of the four plates were all >0.75. From single-point screening of the Prestwick collection, four compounds had percent inhibition values above the 30% threshold (Fig. 6A). The compound distribution data scatter as shown in the histogram (Fig. 6B) and box plot (Fig. 6C) shows a normal (unskewed) distribution with a mean set to zero. Two of the four compounds confirmed with dose response in this assay (Table 2), including propidium iodide with an IC_{50} value of 28 μ M (Fig. 6D), yielding an overall hit-rate of 0.2%.

(B) Histogram of screening data showing a normal distribution. (C) Box plot representing quartiles and outliers. (D) Dose response confirmation for active compound PWK-433663 (propidium iodide) showing a 28 μM IC_{50} value (average of three independent determinations).

GAPDHS HTS and Inhibitor Identification

To identify inhibitors of human GAPDHS, a diverse collection of 28,880 small organic molecules selected from the purchased Asinex set was screened in 384-well format (90 plates) at 10 μM single point concentration. Actives were identified using a standard deviation based-hit threshold ($\mu+3\sigma$). GAPDHS percent inhibition values were plotted for each compound (Fig. 7A). The compound distribution data scatter as shown in the histogram (Fig. 7B) and box plot (Fig. 7C) shows a normal (un-skewed) distribution and a standard deviation in compound data of 8.8%. The average Z' for this screen was 0.88. Thirty one active compounds exhibiting GAPDHS inhibition values above the 30% threshold were identified (Fig. 7A) for a primary hit rate of 0.1%.

Dose response/ IC_{50} determinations were conducted for compounds identified as single-point actives. Data from these assays were analyzed in ActivityBase and plots were assessed for IC_{50} and Hill slope values. Of the 31 compounds tested in dose response, nine compounds exhibited sigmoidal dose response behavior and were confirmed as hits with IC_{50} values ranging from 1.8 to 42.5 μM for an overall confirmation rate of 29% (Table 3). Inhibition by three other compounds (12-14 in Table 3) was trending upwards at the highest doses tested. A second round of screening of the remaining Asinex collection yielded two more hits after confirmation (10 and 11 in Table 3). For all fourteen hits, the percent inhibition values from the primary screen, IC_{50} values and Hill slope values are shown in Table 3. The dose-response curve for the most potent GAPDHS inhibitor identified from the diversity screen, (compound 3), is shown in Fig. (8) and exhibits an IC_{50} value of 1.8 μM and a Hill slope of 1.1.

Table 2. Inhibitors of Human GAPDHS Identified from a Pilot Screen of the Prestwick Set

No.	Compound ID ^a	Name	Structure	% Inhibition in HTS	IC ₅₀ (μM) ^b	Hill Slope Value ^c
1	PWK-433663	Propidium iodide		69.2	28	1.01
2	PWK-433331	Menadione		37.9	40% inhibition at 80 μM	1.10

^aPrestwick chemical identifier number.

^bFor IC₅₀ determinations, serial dilutions of compounds were tested starting at a high concentration of 80 μM. If 50% inhibition was not achieved at top dose, value is shown as % inhibition at 80 μM.

Compounds were pre-spotted (0.5 μl) into 384-well plates and the human GAPDHS enzyme assay carried out in a final volume of 50 μl as described in the materials and methodology. (A) Scatterplot showing percent inhibition values for compounds screened and with actives shown as diamonds above a 3 sigma threshold. Positive controls are shown in green, negative controls in blue and Asinex compounds in black. (B) Histogram of screening data showing a normal distribution and, (C) Box plot representing quartiles and outliers.

To assess hits based on both potency and molecular weight, values were calculated for ligand efficiency (LE) and binding efficiency index (BEI) (Table 3). These parameters allow inhibitor activities to be compared independent of possible molecular weight biases [29, 30]. Based on IC₅₀ values, compounds 2 and 3 were the most inhibitory (6.5 and 1.8 μM, respectively, Table 3). These compounds have a relatively low molecular weight (216 and 207 Da, respectively) and maintained their potent inhibitory ranking after using LE and BEI equations to normalize inhibitory activity to molecular weight among the compounds identified in our screen. An order of magnitude higher IC₅₀ (16.8 μM) was observed for compound 4 (170 Da), though the relative potency of this inhibitor increased significantly after normalization. Of the inhibitors yielding a dose-response curve, compounds 6 and 7 (among the highest MW in the set) had the weakest LE and BEI rating, while their IC₅₀ values were

mid-range. LE values varied from 0.21 to 0.55 kcal mol⁻¹ non-H atom⁻¹; while BEI ranged from 11 to 28. In general, comparable LE and BEI values were obtained. In both cases higher numbers correspond to increased efficiency.

Compounds eliciting dose-response curves using the GST-GAPDHS were also tested against the his-GAPDHS form of the enzyme that we have recently produced using the baculovirus/insect cell system [22]. All of the compounds tested had comparable IC₅₀ values on both GAPDHS enzymes (Table 3).

To assess selectivity of the GAPDHS hits versus the somatic form of GAPDH, the GAPDHS hits were tested for dose-response in a comparable assay using commercially available somatic GAPDH purified from human erythrocytes (Sigma). The assay for human GAPDH was first validated

Table 3. Activities of Confirmed Hits from Chemical Library Screen of Recombinant Human GAPDHS

^aFor IC₅₀ determinations, serial dilutions of compounds were tested starting at a high concentration of 80 μM versus the *E. coli* expressed GST-GAPDHS. If 50% inhibition was not achieved at top dose, value is shown as % inhibition at 80 μM. IC₅₀ values are the average for at least three independent determinations.

^bIC₅₀ and Hill slope values determined by XLfit software (ID Business Solutions).

^cLE: ligand efficiency ($\Delta g = \Delta G N_{\text{non-H atom}}^{-1}$), a measure of the binding energy of the ligand per non-hydrogen atom [30].

^dBEI: binding efficiency index ($\text{BEI} = -\log \text{IC}_{50} \text{ MW}^{-1}$) a measure of the binding affinity of the ligand per ligand molecular weight [29].

^eN/A not applicable, as a dose response curve was not generated.

^fIC₅₀ determinations from dose response against the baculovirus expressed his-GAPDHS [22]. Values determined by XLfit software (ID Business Solutions). ND, not determined.

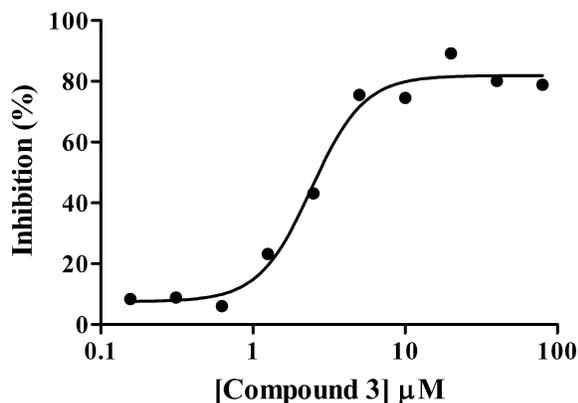

Fig. (8). IC₅₀ value determination for compound 3. Compound 3 was serially diluted in DMSO and the dose response assay carried out as detailed in materials and methodology and then transferred to assay plates for the GAPDHS enzyme assay. The 1.8 μM IC₅₀ value for compound 3 was calculated from the average of three independent determinations.

(data not shown) using procedures previously described for the GAPDHS assay. For a subset of compounds, the corresponding IC₅₀ values versus the somatic GAPDH along with

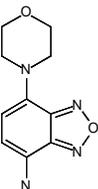

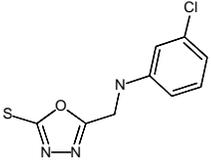

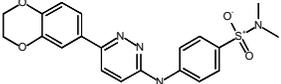

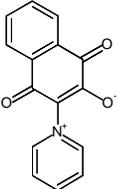

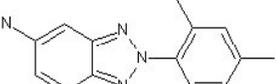

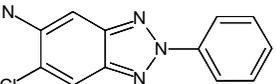

compound structures are shown in Table 4. For compounds 8 and 9 we observed no statistically significant differences between the IC₅₀ values for sperm GAPDHS versus somatic GAPDH. Because the remaining compounds in Table 4 did not yield complete dose response curves we could not conclude whether there were any statistical differences between the two isozymes.

K-means clustering was performed to group compounds by similarity with a 0.65 cutoff. Two of the 14 compounds (compounds 13 and 14) that showed some inhibition of GAPDHS were of the same scaffold. The remaining 12 compounds were structurally unrelated.

Follow Up Assays

To further confirm GAPDHS hits and eliminate false positives, a series of follow up assays were carried out. Two of the confirmed compounds (displaying full dose response) from Table 3 (compounds 4 and 6) were repurchased from Asinex as dry powders to test in follow up assays. Using dry powder, compound 6 (Table 3) had an IC₅₀ value of 13 μM (Fig. 9) very close to that observed (11 μM) from dose response using master plate derived compound (Table 3). Further, this compound had a comparable IC₅₀ value of 17 μM

Table 4. Recombinant GAPDHS Activity Versus Somatic GAPDH and Structures for a Subset of GAPDHS Hits

Compound No.	Structure	GAPDHS IC ₅₀ (μM) ^a	Somatic GAPDH IC ₅₀ (μM)
8		36.1	54.9
9		42.5	66.4
10		45% inhibition at 80 μM	<30% inhibition at 80 μM
12		30% inhibition at 80 μM	<30% inhibition at 80 μM
13		30% inhibition at 80 μM	<30% inhibition at 80 μM
14		30% inhibition at 80 μM	<30% inhibition at 80 μM

^aFor IC₅₀ determinations, serial dilutions of compounds were tested starting at a high concentration of 80 μM. If 50% inhibition was not achieved at top dose, value is shown as % inhibition at 80 μM. IC₅₀ values determined by XLfit software (ID Business Solutions).

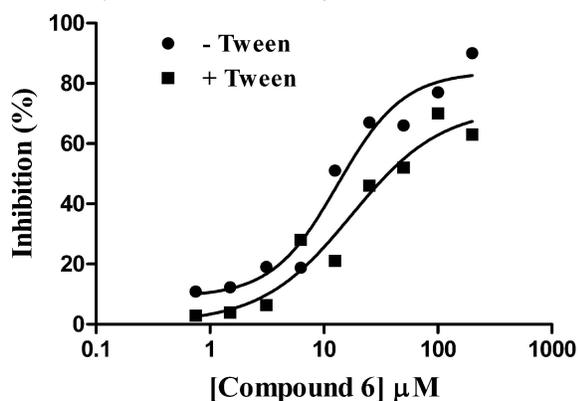

Fig. (9). IC₅₀ value determinations for compound 6 in the presence and absence of detergent. Compound 6 was serially diluted in DMSO and the GAPDHS enzymatic assay carried out in the absence or presence of 0.01% Tween-20.

when tested in the presence of 0.01% Tween-20 (Fig. 9). Menadione, identified from the pilot screen of the Prestwick

set (Table 2), also displayed comparable IC₅₀ values of 47 μM and 53 μM respectively when tested in the absence and presence of 0.01% Tween-20.

These compounds were also assessed for their ability to interfere with the GAPDHS enzymatic assay. The GAPDHS assay was first run kinetically in the absence of any compound until an A₃₄₀ of ~0.7 was reached. Compounds were then added to a final concentration of 50 μM and the A₃₄₀ read again immediately after compound addition. The resulting A₃₄₀ values for the GAPDHS assay with menadione, compound 4 and compound 6 were essentially unchanged at 0.78, 0.67 and 0.69, respectively, suggesting that these compounds do not quench the NADH signal.

DISCUSSION

GAPDHS is expressed only in male germ cells and is required for sperm motility and male fertility [10]. It is an essential enzyme in the central metabolic pathway of glycolysis and is the only GAPDH isozyme in sperm. Conse-

quently, GAPDHS has been proposed as an excellent contraceptive target, particularly if this isozyme can be selectively inhibited without blocking the somatic GAPDH enzyme found in all other tissues. We were able to produce human GAPDHS by expression of a GST-GAPDHS fusion protein in an *E. coli* strain lacking endogenous GAPDH, and the availability of this enzyme provides an excellent basis for the identification of compounds that inhibit the activity of human GAPDHS. The GST-GAPDHS was pure as judged by SDS-PAGE and existed predominantly as a tetramer as assessed by analytical size exclusion chromatography. It is unclear why some of the GST-GAPDHS eluted in the void volume, although this may be due to the solubility of the enzyme when produced in *E. coli* or due to increased enzyme association due to the GST tag. Although some of the GST-GAPDHS protein eluted at the void and is presumably aggregated, this GST-GAPDHS enzyme preparation had a higher specific activity (46 U/mg) than the his-GAPDHS form (28 U/mg) that we have recently expressed in the baculovirus/insect cell expression system [22].

We first adapted and validated an HTS assay in 384-well format based on a standard GAPDH spectrophotometric assay [23] to measure inhibition of recombinant human GAPDHS activity. The assay signal was demonstrated to be proportional to GAPDHS enzyme concentration and up to 5% DMSO was tolerated in the assay. As assessed by whole 384-well plate min-max variability experiments, the assay was robust with Z' values >0.8 and the assay window was stable for 60 minutes allowing ten plates to be run in a single batch. Alpha-chlorohydrin has been reported as a GAPDHS inhibitor (reviewed in [11]), with its metabolite S-3-chlorolactaldehyde being the actual inhibitory form [34, 35]. Our attempts to generate S-3-chlorolactaldehyde and test it as an inhibitor of GAPDHS are ongoing. In the absence of a GAPDH control inhibitor, a no enzyme addition was used as the minimum control with the expectation that the Z' would be higher relative to using a known inhibitor for the minimum control.

We and others have determined that a test screen of a diverse set of compounds such as the Prestwick set has great value in evaluating an assay's response to compounds with varied structures (rather than evaluating with just DMSO) under HTS conditions [31]. The value of the Prestwick collection is that it may also yield interesting inhibitory compounds that already have a wealth of associated data [36, 37]. Screening of the 1,120 compound Prestwick collection against recombinant human GAPDHS, yielded two confirmed inhibitors, propidium iodide and menadione. One of these compounds, menadione, was previously identified as a non-selective inhibitor of GAPDH isozymes *in vivo* (PMID: 12788228, PMID: 2353814). To our knowledge, no reports of propidium iodide inhibiting GAPDH enzymes have been published. Both menadione and propidium iodide were also identified as actives [22] when we subsequently screened the Prestwick collection against the purified his-GAPDHS expressed in the baculovirus/insect cell system.

We used the validated GAPDHS high throughput assay to screen a diverse library of small molecules to identify inhibitors of GAPDHS activity. From the screen, confirmed inhibitors of GST-GAPDHS had IC_{50} values ranging from 1.8 to 42.5 μM . As an additional confirmation, we also tested

those compounds eliciting dose-response curves versus the his-GAPDHS form of the enzyme that we have recently produced using the baculovirus/insect cell system [22] and comparable IC_{50} values were obtained on both forms of GAPDHS.

Hits identified during the high-throughput screen varied in potency. This variation may correlate directly to ligand molecular weight. Two related equations have been introduced to normalize potency to molecular weight to improve comparisons of ligand activity. Ligand efficiency (LE) normalizes binding energy to the number of non-hydrogen atoms in the ligand [30], whereas the binding efficiency index (BEI) normalizes binding affinity to ligand molecular weight [29]. The latter index was introduced to account for large MW differences apparent among diverse heteroatoms [29]. We used both equations to divorce ligand inhibitory activity from a possible MW bias in our data. In general, the different equations yielded comparable results (Table 3). Ranking compound activity by IC_{50} or LE/BEI would result in asymmetric lists, suggesting molecular weight affects the observed IC_{50} values. While the relative ranking of some inhibitors improved upon normalization (notably compound 4), the most potent and relatively low molecular weight compounds (compounds 2 and 3) remained at the top of both lists, suggesting at least three promising GAPDHS inhibitory hits have been identified in this study.

A critical phase of hit confirmation is to distinguish those compounds that are targeting the enzymatic activity from those that might be acting as false positives [32]. Dose response behavior was used to confirm hits identified during HTS. The confirmation rate of 29% suggested that a number of false positives may have been eliminated during dose response testing. False positives may act by interfering with assay read-out, chemically modifying the enzyme or by aggregation-based affects [38]. Compounds with dose-response curves were further analyzed using Hill slope values. Those with high Hill slopes (>2) would typically be eliminated to avoid compounds that may act as aggregators or covalent-modifiers [38]. The majority of confirmed GAPDHS inhibitors had Hill slope values between 0.9 and 1.1, with none having values >2 . However, at this stage we did not eliminate any hits based solely on Hill slope value, since compounds acting allosterically or irreversibly may also have interest as potential leads as GAPDHS inhibitors. Another mechanism of artifactual inhibition is compound aggregation followed by interaction with the enzyme [38-40]. This inhibition can be distinguished by its detergent sensitivity and a counter-screen using low concentrations of detergent was able to discriminate between classical 1:1 inhibitors and promiscuous aggregators [38, 39]. We used a concentration of Tween-20 (0.01%) at the higher end of the range of suggested detergent concentrations [39], to assess whether inhibition profiles were detergent-sensitive or detergent-resistant. We found that inclusion of Tween-20 had no effect on the inhibition profile of compound 6, indicating that it is a standard 1:1 reversible inhibitor. Assays based on measuring absorbance are also susceptible to compound-dependent interference [31, 32]. This was minimized in part by running our assay in kinetic mode. In addition, to assess compound interference, we used a filter assay in which compound is added after completion of the enzymatic reaction and the absorbance immediately read. For those compounds that we

tested from dry powder (compounds **4**, **6**, **10**, **11**, **12** and menadione), we did not observe any compound-dependent quenching of the NADH signal.

All the compounds identified as confirmed hits in Table 3 will be either re-sourced as dry powders or resynthesized for further confirmation and biological testing. Unfortunately, the most active compound (compound **3**, Table 3) is unavailable through any commercial supplier so we are currently planning to synthesize it. Compounds will be tested in counterscreens described herein to assess detergent sensitivity and assay interference. Isothermal calorimetry will also be used to measure the stoichiometry of binding. Confirmed hits will then be tested for their ability to inhibit sperm function, including effects on quantitative parameters of sperm motility determined by computer-assisted sperm analysis (CASA) and CASAnova, a recently developed support vector machines model [41].

A number of approaches will be taken to identify additional GAPDHS inhibitors, including substructure searches to identify similar compounds from our in house library and external libraries, and using structure-based drug design which has already proved successful for targeting GAPDH in parasites [15, 18-20]. Structures for human GAPDHS are available in the pdb database (3PFW and 3H9E) and will be used for assessing both our current hits and for structure-based drug design approaches. Alternative assay formats may also be utilized for additional screens including coupled assays for GAPDHS [42] and those using the resazurin/diaphorase system [43].

Structures and selectivity data for those compounds not included in Table 4 were not disclosed for intellectual property considerations. Additional studies using purchased powders are underway to further evaluate these compounds and identify others that inhibit GAPDHS, focusing on those that exhibit the highest potency and selectivity for the sperm isozyme. Those GAPDHS inhibitors showing little selectivity versus the somatic form may still have utility as molecular probes to assess the role of GAPDHS in sperm function. Details on the mechanism of action, structure-activity relationships, selectivity, and activity in sperm assays of the most potent GAPDHS inhibitors will be detailed in a forthcoming manuscript.

CONCLUSION

A high throughput assay for sperm-specific glyceraldehyde-3-phosphate dehydrogenase (GAPDHS) was optimized and validated for the identification of small molecule inhibitors. The robustness of the GAPDHS primary assay was confirmed by whole plate variability studies. Screening of a small molecule diversity library identified a number of inhibitors of recombinant human GAPDHS with IC₅₀ values ranging from 1.8 to 42 μ M. These compounds may provide useful scaffolds as molecular tools to probe the role of GAPDHS in sperm function or for developing potent and selective GAPDHS inhibitors leading to novel contraceptive agents.

ACKNOWLEDGEMENTS
